Symptoms.—In organic hour-glass stomach a history of comparatively slight indigestion occurring intermittently for many years, possibly with one or more hæmorrhages, can almost always be obtained. The symptoms are similar to those of pyloric obstruction due to ulcer, with the exception that the amount vomited is generally less, and greater relief is obtained on lying down. There is no visible peristalsis unless the proximal segment is unusually large. The X-Rays are the only reliable method of diagnosis; the constriction can be seen whether the patient is standing or lying down, and in the former position the neck passes from a point somewhat above and to the right of the lowest part of the proximal segment. If an active ulcer is present, the niche produced by the crater is seen on the lesser curvature.

Treatment.—If no niche is present and the upper sac of the stomach is empty in under 6 hours, the patient often keeps perfectly well by following the "post-ulcer regime" (p. 586). If the ulcer is still active, surgery is indicated. When the constriction is sufficiently narrow to produce definite stasis in the proximal sac, a gastro-gastrostomy should be performed. If this is impossible for technical reasons, or if there is little or no stasis in the proximal sac, a partial gastrectomy should be performed. As an hour-glass constriction is occasionally associated with pyloric obstruction, the condition of the pylorus should always be investigated in case a gastro-jejunostomy is required in addition to a gastro-gastrostomy.

PYLORIC OBSTRUCTION

Ætiology.—Pyloric obstruction may be organic and incurable or functional and curable. Organic obstruction is caused by the contraction of fibrous tissue formed during cicatrisation of an ulcer in its neighbourhood, 85 per cent. being duodenal and 15 per cent. prepyloric. Two-thirds of all cases of carcinoma of the stomach involve the pylorus. Syphilis is a rare cause of pyloric obstruction. In infants, obstruction may result from hypertrophy of the pyloric sphincter (p. 595).

External pressure very rarely causes pyloric obstruction, and simple adhesions between the pylorus and the neighbouring viscera do not, as a rule, interfere with the passage of food into the duodenum. In exceptional cases, however, cholecystitis may lead to such strong and extensive adhesions with the pylorus that a certain amount of obstruction results. Gastroptosis never causes pyloric obstruction (*vide* Visceroptosis, p. 724).

The œdema and congestion round an active duodenal or prepyloric ulcer may cause severe obstruction, which disappears when the ulcer heals as a result of treatment. In such cases the obstruction is exaggerated by the presence of achalasia or spasm of the sphincter, which may also occur with an ulcer on the lesser curvature and with cholecystitis and appendicitis.

Symptoms.—In the early stages attacks of severe pain may occur at vary-

ing intervals after meals owing to the violent peristalsis of the stomach in its attempt to overcome the obstruction. Later, nothing more than an unpleasant sense of fullness is experienced, especially after meals, but if frequent vomiting or treatment by lavage prevents the stomach from becoming much distended, attacks of pain are likely to persist. With an ordinary diet vomiting occurs regularly every day, but this characteristic symptom is less marked if the patient takes food which leaves little or no solid residue. The vomiting generally occurs at first in the afternoon or evening; but in the later stages, when dilatation has supervened, large quantities are vomited several times a day and often during the night. Articles of food may be brought up which have been eaten many hours or even days before. The odour is sour in non-malignant and rancid in malignant cases. In malignant obstruction excessive fermentation and putrefaction may give rise to very offensive eructation, and in rare cases this is the first symptom noticed by the patient. Wasting is progressive, and the tissues become abnormally dry and inelastic; in malignant cases a cachectic appearance is added to the simple starved appearance of non-malignant obstruction. The patient has generally little appetite, but complains of great thirst. The urine is scanty, and obstinate constipation occurs.

Pyloric obstruction occasionally gives rise to tetany and to symptoms simulating uræmia, but although there is a considerable rise in the blood urea the condition is caused by chloride deficiency and alkalosis and not renal insufficiency.

In addition to the symptoms already enumerated, others depending upon the cause of the obstruction, such as ulcer or carcinoma, are, of course, also present.

Pyloric obstruction leads to distension of the stomach. The signs of this, together with the distinctions between the malignant and non-malignant cases, are considered in the section on the examination of the stomach.

Treatment.—The treatment of organic pyloric obstruction is surgical. It is useless to waste time in well-marked cases with lavage or other medical treatment, as the improvement which follows operation is immediate and progressive. The immediate mortality of the operation can, however, be greatly reduced by preliminary medical treatment for a few days. The stomach is completely emptied every night by Senoran's evacuator. Small quantities of custard, junket and similar soft easily digestible foods, but no fluids, are given during the day, saline solution being given by rectum or, if necessary, subcutaneously. By this means the tone of the stomach rapidly improves, and the danger of severe intoxication due to alkalosis is overcome.

When the obstruction is only partial, and an active ulcer is present, the effect of medical treatment of the ulcer should be tried, as the obstruction is largely due to the surrounding inflammation, which disappears when the ulcer heals, and when healing is rapid the scar generally gives rise to no obstruction.

ARTHUR F. HURST.

CONGENITAL HYPERTROPHY OF THE PYLORUS

Synonym.—Hypertrophic Pyloric Stenosis.

Definition.—This is a disease of early life, formerly believed to be a rarity, but now recognised as of not uncommon occurrence. It consists essentially in a great thickening of the pylorus, leading to gastric stasis, with all the symptoms that result from such a condition.

Ætiology.—The pathogeny of the disease is still obscure. The theory that it is simply a congenital malformation is not in harmony with the clinical facts, and the most generally accepted view is that it results from an overaction of the pyloric sphincter, the consequence of a lack of co-ordination between the gastric and pyloric mechanisms. There is some reason to suppose that the Anglo-Saxon and Teutonic races are more affected by the disease than the Latin, but it is exceptional to get a history of other cases having occurred in the family. Boys are affected at least four times as often as girls, and in a remarkably high proportion the patient is the first child of the family.

Pathology.—The most striking change is an immense thickening of the pylorus, due to overgrowth of its circular muscle-fibres. The stomach is dilated, its muscular coat somewhat hypertrophied, and the mucous membrane in a state of catarrh. The other post-mortem appearances are those usually met with in inanition.

Symptoms.—The child has usually been born at full time, after a natural labour, and in the majority of cases has been breast fed. For a week or two or longer all goes well, and then vomiting sets in. The vomiting is "projectile" in character, the stomach contents being violently shot out. The vomit is usually larger in quantity than the last meal, and is often mixed with mucus; the presence of any blood in it is very rare. Meanwhile the child steadily loses weight, but does not look really ill, and maintains his strength and activity. The bowels are obstinately constipated, and the motions small and dark.

The most characteristic sign of the disease is the presence of *visible gastric peristalsis*. On inspection of the abdomen waves of contraction can be seen sweeping across its upper part from left to right. Sometimes three such waves can be seen at once, each being about the size of a golf ball. The waves may not be seen unless the child has recently been fed, and if they are sluggish in appearing a little gentle stimulation below the left costal margin will often succeed in eliciting them. In most cases the overgrown pylorus can be felt as a tumour by pinching up the deep structures in the right hypochondrium. Sometimes, however, it is so tucked up under the liver that it cannot be felt.

Complications and Sequelæ.—The complication most to be dreaded is the supervention of an infective diarrhœa, which in these cases is very apt to prove fatal. Some degree of acidosis is also apt to develop in severe cases. There are no sequelæ of the disease; if recovery takes place, it is complete and permanent, and indeed, many of the patients ultimately attain a degree of health and development beyond the average. The hypertrophy of the pylorus disappears.

Course.—The course of the disease varies greatly in different cases, and depends also to a large extent upon the treatment adopted, but unless operation is resorted to, it is always prolonged and recovery gradual. Even when the vomiting ceases, the weight may for long fail to rise, and the child may remain in a state of inanition, during which intercurrent disease may easily supervene.

Diagnosis.—This should not be difficult, provided the existence of the disease is remembered. The vomiting is distinguished from that of indigestion by its projectile character, and the coexistence of constipation is char-

acteristic. The great diagnostic, however, is the presence of the visible peristalsis, and in the absence of this it is unwise to conclude that the disease is present. Mild cases of pyloric spasm may simulate true stenosis, but in these the symptoms are less severe, and definite waves of peristalsis are absent. The patient is often a girl. Stenosis of the duodenum from congenital malformation may simulate pyloric stenosis, but the symptoms in the duodenal cases date *from birth*, and bile is present in the vomited matter.

Prognosis.—It is very difficult to estimate the chances of recovery or the relative merits of different forms of treatment statistically. Much depends upon the severity of the particular case, but in general it may be stated that no case is so severe that recovery is impossible. Cases treated in private do much better than those seen in hospital.

Treatment.—There are two methods of treatment—medical and surgical. Medical treatment consists in washing out the stomach once or twice daily with warm water, and carefully regulating the feeding. If breast milk is not available, dilute peptonised milk is the best substitute, and should be given in quantities of one or two ounces every 2 or 3 hours, depending upon the degree of vomiting. Atropine (3 to 9 drops of a 1 in 1000 solution of the sulphate, half an hour before each feed) is sometimes used on the Continent, with alleged benefit. If under this treatment the vomiting ceases, and the weight begins to rise, good and well. If not, or if the symptoms have set in early and with great severity, operation should be had recourse to, Rammstedt's plan of splitting the pylorus longitudinally being the procedure to be preferred.

ROBERT HUTCHISON.

ACUTE DILATATION OF THE STOMACH

Ætiology.—After operations, especially for acute abdominal conditions, and much less frequently in the course of acute infections, especially pneumonia, the stomach suddenly becomes greatly dilated owing to a complete loss of tone. The acute dilatation, which is often much aggravated by severe aerophagy, leads to complete obstruction of the duodenum by the mesentery at the point where the latter crosses it, and the dilatation then becomes extreme.

Symptoms.—The abdomen is very distended, large quantities of dark but not faecal fluid are vomited, and the patient rapidly becomes very collapsed. "Black vomiting" after operations is almost always due to acute dilatation of the stomach and not to the intestinal paralysis with which it is often associated.

Treatment.—The stomach should be kept empty by aspirating through a Ryle tube kept continuously in position, however ill the patient may be. Nothing should be given by the mouth, but saline solution should be injected into the rectum or subcutaneously. If recovery does not occur in two or three days, a jejunostomy should be performed, the patient being fed through the stoma till the stomach contracts to its normal size.

CHRONIC DUODENAL ILEUS

Ætiology and Pathogenesis.—Just before the duodenum turns upwards to end in the duodeno-jejunal flexure, it is crossed by the root of the

mesentery. When the mesenteric vessels arise at a lower level than usual or the horizontal portion of the duodenum is situated unusually high, the slight anatomical variation from the average normal is enough to lead to some narrowing of the lumen of the duodenum where it is crossed. If the abdominal muscles are lax and the small intestines drop into the pelvis, they may be partially incarcerated there and the obstruction becomes more marked. In rare cases obstruction at the same point is caused by localised simple or tuberculous chronic peritonitis. The proximal part of the duodenum becomes dilated (Fig. 17), and the violent peristalsis, which can be seen with the X-Rays to give rise to backward and forward movements of its contents in its effort to pass the obstruction, results eventually in hypertrophy of its muscular coat.

FIG. 17. — Chronic duodenal ileus. DD, dilated duodenum secondary to obstruction by MV, mesenteric vessels; P, pylorus; CD, undilated duodenum beyond obstruction merging into jejunum.

Symptoms — The condition generally gives rise to no symptoms and is discovered accidentally during a routine X-Ray examination, but it may cause right-sided discomfort, which sometimes simulates duodenal ulcer or gall-bladder disease. Occasionally paroxysmal vomiting is the only symptom, especially in neurotic women, and in rare cases it is the cause of cyclical vomiting in children, which persists into adult life. The duodenal stasis may be a factor in the development of duodenal ulcer and of cholecystitis, when chronic ileus is present in an individual who is already predisposed to these conditions. An anterior duodenal ulcer associated with ileus is specially liable to perforate.

Treatment. — In most cases postural treatment gives complete relief. The patient should for a few weeks adopt a position for a quarter of an hour every day in which the X-Rays have shown that the obstruction is overcome. Lying on the right side or face downwards may be sufficient. In more severe cases the patient leans over the end of a couch with his head downwards, so that his trunk is perpendicular to the ground; this allows the incarcerated small intestine to drop out of the pelvis, and complete permanent relief may follow.

In my experience the results of duodeno-jejunostomy have only been satisfactory when the obstruction is sufficient to cause considerable duodenal stasis. In neurotic women with paroxysmal vomiting the symptoms almost invariably recur after a short interval of freedom.

When a duodenal ulcer is associated with duodenal ileus the danger of perforation calls for operation: gastro-jejunostomy is often successful, but it is sometimes followed by persistent vomiting, so that a duodeno-jejunostomy should probably be performed at the same time, or preferably a partial duodeno-gastrectomy should replace both operations.

ARTHUR F. HURST.

DISEASES OF THE INTESTINES

INTRODUCTION

I. THE FUNCTIONAL DIVISIONS OF THE INTESTINES

i. *The small intestines.*—In the duodenum the food is mixed with the pancreatic juice, which is essential for the digestion of protein and fat, and with bile, which promotes the absorption of the products of digestion of the latter. In its passage through the small intestine the chyme is mixed with the succus entericus, which contains an amylolytic ferment, deficiency of which leads to carbohydrate dyspepsia, although this is never caused by deficiency of the ptyalin of the saliva or the amylopsin of the pancreatic juice. The chyme passes rapidly through the jejunum and greater part of the ileum, in the last 12 inches of which it remains for a considerable time. The terminal ileum indeed forms an "ileal stomach," in which the greater part of the digestion of protein, fat and carbohydrate by trypsin, steapsin and the intestinal diastatic ferment respectively takes place and the products of digestion are absorbed.

ii. *The proximal colon.*—Observations on patients with cæcal fistulæ show that about 350 grms. of fluid chyme, containing 90 per cent. of water with small quantities of sugar, fat, coagulable protein and the soluble products of their digestion, pass through the ileo-cæcal sphincter in a day. As the average weight of fæces is 135 grms. and they contain only 75 per cent. of water with no sugar, coagulable protein or soluble products of digestion, it is clear that much water and all the soluble constituents of the chyme which reach the cæcum must be absorbed in the colon. This absorption takes place in the cæcum, ascending colon and proximal half of the transverse colon, which may therefore be regarded as the "colonic stomach."

iii. *The distal colon.*—The pelvic colon acts as a storehouse for fæces, to which they are conveyed through the distal part of the transverse colon, the descending colon and the iliac colon when digestion in the colonic stomach is complete. Here they remain until the time for defæcation arrives. The distal colon is thus concerned solely with excretion.

iv. *The rectum.*—The rectum has the important function of maintaining the regular evacuation of fæces. It is generally empty, and the distension of its walls when fæces enter it is the normal afferent impulse which gives rise to the defæcation reflex; the same impulse produces the sensation which prompts the individual to perform the voluntary acts which help in the efficient performance of the reflex.

II. THE INTESTINAL MOVEMENTS

The movements of the intestines have two main objects: (1) mixing the food with the digestive juices and bringing them into contact with the mucous membrane by which the products of digestion and water are absorbed, and (2) propulsion of its contents from the duodenum to the rectum, and of the indigestible residue of the food from the rectum.

i. *The small intestines.*—In the small intestine peristalsis and segmenta-

tion take place simultaneously, the former with the object of propelling the chyme into the "ileal stomach," and the latter with the object of mixing the food with the digestive juice and exposing it to as large an area of mucous membrane as possible during its passage. In the jejunum and greater part of the ileum peristalsis is the predominating motor activity, but when the ileal stomach is reached it ceases almost completely for a time, and segmentation becomes extremely active. After a varying interval peristalsis becomes active again and, as the ileo-cæcal sphincter relaxes with the arrival of each peristaltic wave, the ileal stomach empties its contents into the cæcum.

ii. *The colon.*—When the colon is examined after an opaque meal it appears to be completely immobile. In spite of this, both segmentation and peristalsis occur under normal conditions in the colon, but their character differs considerably from the corresponding movements in the small intestine. Peristalsis occurs only in the form of "mass movements" about three times a day. A single very powerful peristaltic wave travels slowly along a considerable part or even the whole length of the colon, pushing in front of it most of the contents. Deep segmentation movements, which are too slow to be visible with the naked eye, can be recognised by comparing radiograms taken at three-minute intervals and often in those taken at intervals of a single minute. These movements are only partly due to contractions of the muscular coat of the colon, the majority of them being the result of the ceaseless activity of the *muscularis mucosæ* causing movements of the mucous membrane, which constantly forms new projections into the lumen of the colon. As a result of the continuous segmentation in the colonic stomach much of the water and all of the soluble constituents of the food and the products of their digestion which have escaped the small intestine are absorbed.

The chyme leaves the ileal stomach very slowly except during and immediately after meals, when as a result of a gastro-ileo-cæcal reflex frequent peristaltic waves pass down the terminal ileum to the ileo-cæcal sphincter, which opens widely as each wave reaches it. The chief stimulus to mass peristalsis of the colon is a similar gastro-colic reflex. On comparing these events it becomes clear that the ileal stomach passes its contents into the cæcum when it is necessary that it should be empty for the reception of the food coming down from the stomach after a meal, and that the colonic stomach similarly evacuates itself to leave room for the reception of the contents of the ileal stomach.

III. DEFÆCATION

During defæcation the contents of the pelvic colon, together with any fæces which might be present in the descending and iliac colon, pass into the rectum from which they are evacuated. At the same time the contents of the cæcum and ascending colon pass into the transverse colon, whilst the contents of the latter pass into the pelvic colon. This is the only occasion in the day in which mass peristalsis takes place in the cæcum and ascending colon, mass peristalsis after meals being confined to parts distal to the middle of the ascending colon. Presumably, therefore, the evacuation of the pelvic colon is an essential preliminary for the onward passage of the contents of the cæcum and ascending colon, just as the evacua-

tion of the distal part of the colonic stomach accompanies the evacuation of the ileal stomach and that of the ileal stomach accompanies the evacuation of the gastric stomach.

Normal defæcation depends upon a conditioned reflex. The infant is taught at an early age to empty his bowels directly he is placed on a chamber. The act quickly becomes a purely reflex one, and it continues to be so when he grows older and the chamber is replaced by the seat in the w.c. Breakfast by itself gives rise to a simple gastro-colic reflex; sitting down on the familiar seat in the w.c. is, however, the starting-point of the more elaborate conditioned reflex, which produces the most efficient gastro-colic reflex of the day, in which the whole colon from the cæcum to the rectum takes part. In the healthy adult, defæcation remains to a great extent a conditioned reflex. It is enough to sit down in the accustomed place, perhaps with a pipe and a newspaper, for the reflex to begin, often without the "call to defæcate"—the perineal sensation produced by the entry of fæces into the rectum, and without the voluntary stimulus produced by the increased intra-abdominal pressure caused by descent of the diaphragm and contraction of the abdominal muscles, though these, together with the final contraction of the levator ani muscles, are always brought into action to help in the complete expulsion of the fæces.

Failure to open the bowels on the first day of a holiday is not due, as is popularly supposed, to the "hard water" of the locality, deficient exercise in a train or on board ship, but to the unfamiliar w.c. and perhaps the unusual hour of getting up—or the absence of getting-up, such small change being enough to upset for the moment the delicately adjusted conditioned reflex.

EXAMINATION OF THE INTESTINES

SIZE, SHAPE AND POSITION OF THE COLON

The cæcum and iliac colon are the only parts of the bowel which are always palpable under normal conditions. In very thin individuals and in patients with very lax abdominal muscles the whole colon except the splenic flexure and the pelvic colon can often be felt. Apart from these conditions the colon may become palpable when in a state of spasm or when filled with fæces, and tumours involving it can often be recognised by abdominal examination. In all intestinal cases a rectal examination must be made; by this means not only the rectum but also part of the pelvic colon can be palpated. For a thorough investigation of the size, shape and position of the whole colon in the erect as well as the horizontal postures an X-Ray examination after a barium meal is essential. The pelvic colon, and less frequently the descending and iliac colon, cannot always be seen as satisfactorily, they may only be full in the early morning, and defæcation empties them completely before it is convenient to make an examination. In such cases a barium enema renders all parts of the colon easily visible; the artificial distension produces a considerable amount of distortion, the error due to which can be overcome by making an additional examination after most of the fluid has been allowed to escape.

MOTOR FUNCTIONS

(a) *Palpation*.—In every case of intestinal disorder an abdominal and rectal examination should be made. No medicine or enema should be given during the preceding 24 hours, but before this the colon should be emptied by whatever means the patient is in the habit of using. The quantity of fæces present in each part of the colon varies greatly according to the time at which meals are taken and defæcation occurs. With a normal individual taking his meals at the usual time, whose bowels are satisfactorily opened after breakfast, the whole of the colon is empty during the greater part of the morning, though a thin layer of soft fæces may cover the wall of the cæcum and perhaps the ascending colon and so render them partially opaque to the X-Rays if a barium meal was taken 24 hours earlier, and a small quantity of semi-solid fæces may be present in the distal part of the transverse colon. Between 3 and 4 hours after breakfast the cæcum begins to fill; the filling becomes much more rapid after lunch, so that in a short time the ascending colon also becomes filled. During the rest of the day palpation shows the cæcum and ascending colon, and often the proximal part of the transverse colon, to be filled with soft fæces; as a rule this can be recognised much more easily in the part of the colon in the right iliac fossa, owing to the solid background it affords, than in the more distal part. The resonant note which is generally obtained on percussion over the right half of the colon in the morning is replaced by a dull note in the afternoon.

In the early morning the rectum is empty, but the pelvic colon can be felt through the anterior rectal wall to be filled with solid scybala, which sometimes extend upwards into the iliac and the descending colon. On getting up, but often only after breakfast, the pelvic colon empties some of its contents into the rectum, giving rise to the "call to defæcate"; from this moment until defæcation has occurred is the only time in the day in which the rectum of a normal individual is filled with fæces. At all other times it is completely empty, and a proctoscope shows that there is not even a trace of fæces adherent to the mucous membrane. In defæcation the whole of the colon beyond the splenic flexure empties itself; consequently the descending, iliac and pelvic colon are empty during the whole morning. If some fæces were present in the distal half of the transverse colon in the morning, they pass into the lower end of the pelvic colon with the mass peristalsis which occurs after lunch. With this possible exception the pelvic colon is generally empty or almost empty until after tea or more commonly after dinner, when another wave of mass peristalsis fills it with the contents of the colon from the neighbourhood of the hepatic flexure and the proximal half of the transverse colon.

The details of the movements vary greatly in different individuals, but the average conditions just described show how greatly the fullness of the different parts of the colon varies with the time of day, and how unjustifiable, for example, it is to diagnose cæcal and ascending colon stasis because these parts of the colon are full of fæces when examined in the afternoon.

If the rectum is full of fæces and the patient has no desire to defæcate, dyschezia can be diagnosed. If the fæces are soft it is clear that there can have been no delay in the passage to the rectum, such as is likely to have occurred if it contains hard and dry scybala. When the rectum is empty

but the pelvic colon can be felt through the anterior rectal wall to contain scybala, the form of dyschezia which is due to inability of the pelvic colon to empty its contents into the rectum is present, but this can only be diagnosed with certainty if the patient has made an effort to open his bowels after breakfast and the examination is made before lunch. In severe cases hard scybala may also be felt in the iliac and perhaps the descending colon.

A full cæcum and ascending colon are only of significance if the examination is made within 3 or 4 hours of breakfast; even then primary right-sided stasis can only be diagnosed if the rectum and pelvic colon are empty.

(b) *The Charcoal Method.*—By giving two or three charcoal lozenges with some food 8 hours after defæcation and observing after what interval black fæces are passed, the total time taken in their passage through the alimentary canal can be ascertained. If, for example, a patient's bowels have been opened at 8 a.m., charcoal should be given at 4 p.m. the same day. If some of the charcoal is not passed at latest the second morning after it was taken, the patient must be regarded as constipated. The method has, however, the great disadvantage of giving no indication as to the part of the bowel in which stasis occurs.

(c) *X-Ray Examination.*—The only reliable means of determining whether a patient is suffering from chronic intestinal stasis, and of ascertaining exactly what parts of the alimentary canal are at fault, is a series of examinations with the X-Rays. Examination with the fluorescent screen gives more information than is obtainable from radiograms. If the bowels are not spontaneously opened, an enema should be given on two consecutive mornings, on the second of which the opaque meal is taken. It is very important to discontinue the use of all aperients for at least 48 hours before the first examination, as the intestinal functions might otherwise be observed whilst still under their influence instead of under natural conditions. No more aperients and no enemata should be used till the examination is finished, but the patient should make an attempt each morning to open the bowels naturally. If the attempt is successful, the stools should be examined in order to ascertain whether any of the barium has been evacuated. During the whole period of the examination the patient should follow his usual occupations and take his ordinary diet. An examination should be made in the morning and evening of each day until all or most of the barium sulphate has been passed in the fæces or has reached the rectum.

Although an opaque meal is the best means of obtaining information of the motor functions of the colon, an opaque enema generally gives earlier and more exact information concerning the possible presence of a stricture, especially in the pelvic colon, which often cannot be satisfactorily examined by the former method. A suspension is made by adding 8 oz. of barium sulphate and 4 oz. of kaolin to a pint and a half of water. The patient lies on his back, and the fluid is run in from a container at a pressure of between 1 and 2 feet through a valveless Higginson's syringe connected with a tube introduced just within the rectum, the syringe being used, when necessary, to help the passage of the opaque mixture with light pressure. It often reaches the cæcum in 2 minutes and almost invariably within 5 minutes. Patients rarely experience any difficulty in retaining the fluid until the examination is complete, when part can be run out through the tube by

which it was introduced, the rest being evacuated in the ordinary manner, a further inspection with the X-Ray being then made.

An organic stricture of the colon generally obstructs the passage of the fluid, the shadow ending at the seat of the obstruction, which can be overcome only incompletely or not at all by waiting an additional 10 minutes, by increasing and decreasing the pressure of injection, by massage and by changes in posture. The flow of the enema is often prevented in cases of growth long before there is any clinical evidence of obstruction; the bowels may still act normally or diarrhoea may be present, and an opaque meal may pass through the whole colon without delay. This is probably due to the occurrence of a spasmodic contraction of the bowel, which occurs at the seat of obstruction as soon as the enema reaches and distends the part immediately below it.

An opaque meal or, more frequently, an opaque enema may show the presence of a filling defect in the colon caused by a growth. It also shows the exact length and position of strictures due to other causes, and it is generally the most satisfactory way in which the presence of diverticula can be determined.

EXAMINATION OF FÆCES

The consistence, smell, colour and reaction of the stools when no aperient is being taken should be noted, abnormal acidity indicating excessive fermentation and abnormal alkalinity excessive putrefaction. The presence of mucus with solid stools is not in itself a sign of disease, but if it is mixed with blood or pus, or the stools are soft though no aperient has been taken, some organic disease is certainly present. On the other hand, the presence of mucus with hard scybala or with soft stools obtained after the use of an aperient is due to the normal reaction of the colon to a mechanical and chemical irritant respectively, mucus being secreted in order to protect the mucous membrane. Blood by itself may come from hæmorrhoids; if associated with mucus or pus or both, inflammation or cancer of the anal canal, rectum or colon must be present. The larger the fragments of mucus and the brighter the colour of the blood the lower is their source. The presence of pus always indicates disease of the lower part of the colon or of the rectum; any produced in the small intestines is digested.

Pale, bulky stools generally indicate the presence of excess of fat. It is important to ascertain whether this is chiefly in the form of neutral fat, as in pancreatic insufficiency, or in the form of fatty acids and soaps, as in deficient absorption caused by jaundice, sprue, coeliac disease and obstruction of the lacteals with normal pancreatic digestion. This can generally be decided by microscopical examination, but in doubtful cases an accurate chemical analysis should be undertaken.

Microscopic examination may reveal the presence of blood corpuscles, pus, amœbæ or their cysts, and the ova of intestinal worms, in addition to fragments of animal and vegetable food which have escaped digestion.

A bacteriological examination of the stools should always be made in cases of diarrhoea, with or without colitis. The presence of a relative excess of enterococci or *B. coli communis*, the normal inhabitants of the colon, or of strains of streptococci or *B. coli* which are not normally present, or of parenteric, enteric, dysentery and tubercle bacilli, may be discovered. If

a sigmoidoscopic examination is made, a swab should be taken for bacteriological examination directly from the mucous membrane; if any mucus or pus is seen, this should also be taken for the purpose. In doubtful cases the agglutinating power of the patient's blood for abnormal bacteria isolated from the stools should be tested.

Occult blood.—When blood is swallowed or is derived from an ulcer or growth in the stomach or an ulcer in the duodenum, it is evacuated in the stools partly as acid hæmatin and partly as hæmatoporphyrin. Both also appear in the stools when the blood originates in the colon unless diarrhoea is present, when the blood does not remain in the bowel long enough for the former to be converted into the latter. The chemical tests for "occult blood"—traces of blood insufficient to produce any change in the appearance of the fæces—depend upon the conversion of a substance with little or no colour, such as guaiac or benzidine, into a coloured substance when oxidised by hydrogen peroxide in the presence of a carrier, such as hæmatin. Hæmatoporphyrin, which contains no iron, does not give the reaction. The spectroscopic examination of the stools should also be used, as traces of hæmatoporphyrin, which is occasionally present in the absence of acid hæmatin, would otherwise escape recognition. Moreover, a positive spectroscopic finding is valuable confirmation of a positive chemical reaction, as, although it is much less sensitive, there is less chance of error.

Before examining the stools, the patient is given a hæmoglobin-free diet. Chlorophyll should also be excluded, as it gives a feebly positive guaiac reaction, and its many-banded spectrum may cause confusion in the spectroscopic examination. A charcoal biscuit is given with the first meal on the restricted diet, and the first and subsequent stools passed when the fæces are no longer blackened by the charcoal are examined. For the guaiac and spectroscopic tests a small amount of fæces is macerated with glacial acetic acid into a thin paste. An equal quantity of ether is then added to extract the pigment; the ethereal extract is poured off, some being kept for the spectroscopic examination. Two or three drops of tincture of guaiac are added to the remainder; a small quantity of ozonic alcohol is then poured in, and a change of colour is looked for at the junction of the two fluids. A "positive" reaction is one in which a deep blue colour rapidly appears; a "feebly positive" reaction is one in which the colour is faint purple, bluish, or greenish.

A positive guaiac reaction signifies the presence of occult blood, and a positive spectroscopic examination shows that it is present in fairly considerable quantities. A negative guaiac reaction proves the absence of occult blood, except occasionally at the end of a period of hæmorrhage, when the spectroscopic test may alone be positive, as the traces of blood still present may then be completely converted into hæmatoporphyrin, which gives a characteristic spectrum, but does not give the chemical reactions. Iron taken as medicine gives a positive benzidine but negative guaiac reaction.

In the absence of hæmorrhoids or rectal polypi (which may be quite latent) and of bleeding from the mouth, throat and nose, the presence of occult blood is strong evidence that an ulcer or growth is present in the stomach or intestines. It is also occasionally found in gastritis, gall-stones, diverticulitis and localised adhesions involving the alimentary tract.

PROCTOSCOPIC AND SIGMOIDOSCOPIC EXAMINATION

In all cases in which there is any possibility of organic disease of the pelvic colon or rectum a proctoscope, and, if necessary, a sigmoidoscope should be passed after a preliminary digital examination. No special preparation is required, but the patient should endeavour to get his bowels emptied as completely as possible shortly before the examination without the aid of aperients or enemata. The instrument should be passed without an anæsthetic in the knee-elbow position. If digital examination is painful owing to inflammation of the anal canal, a cocaine semple or diathermy with a rectal electrode should be applied in order to anæsthetise it before the instrument is passed.

FUNCTIONAL DISORDERS OF THE INTESTINES

CONSTIPATION

Definition.—Constipation may be defined as a condition in which none of the residue of the first meal taken after defæcation is excreted within the next 48 hours.

Ætiology and Pathology.—Constipation may be due to (1) the passage through the colon being delayed, whilst defæcation is normal—colic constipation; (2) the evacuation from the pelvic colon and rectum being inadequately performed, whilst the passage through the colon is normal—dyschezia; and (3) insufficient formation of fæces.

1. *Colic constipation.*—Delay in the passage of fæces through the intestines is due to their motor activity being deficient, or to the force required to carry the fæces to the pelvic colon being excessive. The motor activity of the colon may be deficient owing to deficient reflex activity, inhibition, or uncontrolled and irregular action. There is no evidence that it is ever due to actual weakness of the muscular coat. The reflexes which maintain intestinal activity may be deficient owing to lack of mechanical and chemical stimulants in the food, or to deficiency in hormones, as in hypothyroidism. They are also deficient when the excitability of the mucous membrane is impaired as a result of long-continued irritation by purgatives. The inhibitory sympathetic nerves may be stimulated centrally by depressing emotions, and reflexly in painful diseases and injuries of any part of the body, but particularly of the abdominal and pelvic viscera.

Constipation may result from painful spasm, induced reflexly by the presence of an irritant in the colon of a patient with an abnormally excitable nervous system (*spastic constipation*). The irritant which gives rise to the exaggerated reflexes is in most cases hard fæces, which may have been retained as a result of constipation caused by insufficient and unsuitable food and of dyschezia. The reflex may also be excited by disease in other parts of the abdomen, especially chronic appendicitis. Similar spasmodic contractions of the intestines occur as a result of excessive smoking and in lead poisoning.

The work to be done by the intestinal musculature is excessive when

the consistence of the fæces offers more than the normal degree of resistance owing to insufficient consumption of water or its excessive loss in the urine or sweat, and when there is a diminution in the intestinal lumen owing to organic stricture.

2. *Dyschezia*.—Dyschezia may be due to inefficiency of the defæcation reflex, to abnormally hard and bulky fæces requiring excessive force for their evacuation, or an obstacle to efficient defæcation, such as spasm or congenital or acquired strictures of the anal canal. Dyschezia due to inefficient defæcation is the most common cause of severe constipation, and is generally of nervous origin. It often originates in neglect to respond to the call to defæcate owing to laziness, insanitary condition of the w.c., or false modesty. The conditioned reflex upon which defæcation normally depends is gradually lost. The rectum dilates so that an increasing quantity of fæces is needed to produce the adequate internal pressure required to give the sensation of fullness which is the natural call to defæcation. Finally the sensation is lost completely. But the patient is still capable of emptying his rectum if he tries. He has, however, by now often convinced himself that he cannot get his bowels to open unless he takes enemata or such enormous doses of aperients that the fluid fæces practically act as enemata. He thus suggests to himself that his rectum is powerless to act by itself; the dyschezia is then in part hysterical.

Dyschezia may be due to various other causes, such as weakness of the voluntary muscles of defæcation, the assumption of an unsuitable position during defæcation, and voluntary inhibition from fear of pain in diseases of the anus and the neighbouring organs. But whatever the primary cause, the final result is the same. The conditioned defæcation reflex is lost, and the incomplete evacuation of the rectum results in the accumulation of fæces and consequent dilatation of the rectum.

Careful training is required from earliest infancy in order to develop the defæcation reflex. Neglect of this, together perhaps in some cases with a congenital deficiency of the muscle-sense of the rectum, is the cause of the dyschezia of infants, in whom the slight additional distension produced by the introduction of a finger or a piece of soap into the rectum results in an adequate stimulus.

The rectal muscle-sense is abolished or defective in diseases of the spinal cord in which the defæcation centre itself or the fibres connecting it with the brain are involved.

3. The third great class of constipation is due to the quantity of fæces formed being insufficient to produce an adequate stimulus in the pelvic colon and rectum, and to a less extent in the rest of the colon. The insufficient bulk of fæces is due to an inadequate quantity of food residue reaching the colon as a result of anorexia or of œsophageal or pyloric obstruction, or to unusually complete digestion and absorption of food, the result of a "greedy bowel."

Symptoms.—Many people regard themselves as ill if they do not have one action of the bowels a day; but this is really nothing more than a question of convenience, being found to suit the habits and diet of the majority of civilised people. Perfect health may be maintained by individuals who defæcate regularly two or three times a day, and by others who obtain an evacuation once in two, three or more days. The latter, so long as defæcation, when it does occur, is complete, can no more be regarded as diseased than those

otherwise normal people, whose hearts beat only forty or fifty times a minute. The majority, however, although they may suffer no inconvenience for a considerable time, finally develop symptoms due to faecal accumulation, gradually increasing quantities of faeces being retained. For practical purposes, therefore, an individual may be considered constipated if his bowels are not opened at least once in every 48 hours. A less frequently recognised variety of constipation is that in which insufficient faeces are excreted, although the bowels may be opened every day—a condition analogous to retention of urine with overflow.

It is important to distinguish the symptoms of constipation from those of the conditions which may give rise to it. There is no doubt that neurasthenia, hypochondriasis, epilepsy, asthma, nephritis, diabetes, painful pelvic disorders and many other diseases may be greatly aggravated by constipation. Apart from these conditions, headache, mental and physical fatigue, vertigo, anorexia and pigmentation of the skin may result directly from intestinal intoxication and, with the exception of pigmentation, from the reflex effects of constipation. Toxic symptoms rarely develop unless stasis occurs in the caecum and ascending colon, in which the faeces are still soft, and then only if it is associated with impairment of the functional efficiency of the liver, which normally destroys intestinal toxins or renders them innocuous, or of the kidneys, which normally excrete any toxins which have escaped the liver. Reflex symptoms, on the other hand, occur chiefly in dyschezia as a result of the pressure produced by hard faeces. The latter differ from the former by their almost instantaneous disappearance on defaecation.

Faecal retention is a common cause of intestinal flatulence and colic. In rare cases a faecal tumour and faecal obstruction occur. A faecal accumulation in the rectum may cause haemorrhoids, pruritus ani, catarrhal proctitis and neuralgic pains in the back, down the legs, and in the female pelvic organs. Hard faeces make defaecation painful, and their passage may give rise to anal ulcers.

Diagnosis.—It is comparatively rare for a patient to consult a doctor on account of constipation without having already attempted to cure himself with aperients. But no accurate diagnosis can be made until it has been ascertained whether he is actually constipated at all. The symptoms generally ascribed to auto-intoxication caused by intestinal stasis are often really produced by purgatives, which lead to the absorption of excess of toxic material by hastening the half-digested contents of the small intestine into the caecum, where fermentation and putrefaction are consequently increased, and by causing the contents of the transverse, descending and pelvic colon to be fluid instead of solid, so that absorption of toxins continues throughout the length of the bowel instead of in the caecum and ascending colon alone. In spite of his probable protests the patient is instructed to see what happens if no drugs are taken for three days, an effort being made to open the bowels each morning. In most cases he loses his abdominal pain and his so-called toxic symptoms. The bowels are often opened daily, in which case a diagnosis of hysterical pseudo-constipation can be made—hysterical because the patient had suggested to himself, as a result of faulty education combined with the reading of pernicious advertisements, that he was constipated and required aperients to keep himself well, whereas a little psychotherapy, in the form

of explanation of the physiology of his bowels and the origin of his symptoms and persuasion to try to open his bowels each morning without artificial help, results in a cure. In some cases, however, the patient does not succeed in opening his bowels, although he may feel more comfortable than when he was taking drugs. A second abdominal and rectal examination should then be made. If no sign of organic disease is present, and the rectum is found to be filled with fæces, dyschezia can be diagnosed. In spite of this the patient has no desire to open his bowels; a normal individual would feel an urgent call to defæcation under such conditions, but the rectum has dilated as a result of being constantly full of fæces and the call to defæcation is no longer felt.

In severe cases it is advisable to examine the intestinal functions with the X-Rays, a barium meal being given after the patient has discontinued taking aperients. Ileal stasis should only be diagnosed if no trace of barium has reached the cæcum 6 hours after the opaque meal, or if a considerable quantity of barium-containing chyme is still in the end of the ileum 6 hours after evacuation of the stomach is complete. If most of the barium is still

FIG. 18.—Dyschezia in a girl of 17, whose bowels had not been opened for 5 weeks when admitted to Guy's Hospital. (First case of constipation examined with x-rays: May 1907.)

in the cæcum and ascending colon at the end of 24 hours, stasis is present, even if a little has passed to the more distal parts of the colon; but a faint shadow of the cæcum is often visible in normal individuals even 3 days after the meal. If the splenic flexure is reached in 24 hours, and the greater part of the barium is in the transverse colon at the end of 48 hours, there must be stasis in this part of the bowel. In dyschezia most or all of the barium has accumulated in the rectum in 24 hours (Fig. 18). A similar accumulation occurs in the pelvic colon, though the rectum remains empty in pelvic colon dyschezia.

Treatment.—Under no circumstances should the patient fail to make an effort to open his bowels after breakfast, even if he feels no desire to do so, and a call to defæcation felt at any other hour in the day should be obeyed at once, at whatever inconvenient time it may occur. Sufficient time should always be spent over the act of defæcation, and it is often advisable to pay two visits to the closet at short intervals. In order to prevent the temptation to hurry over defæcation, the closet should be clean, devoid of smell, and properly warmed in winter. In dyschezia with weak abdominal muscles a footstool, 9 inches lower than the seat, should be provided, and in severe cases the patient should crouch over a bed-pan placed on the floor. In many

cases of dyschezia no treatment is required beyond explaining to the patient the nature and cause of his condition, and persuading him to give up aperients and to make an effort to empty his rectum, which he must realise is quite capable of doing its work. By perseverance it is generally possible to redevelop the lost conditioned reflex upon which normal defæcation depends.

It is most important to see that sufficient food is taken, as constipation is often as much due to its insufficient quantity as to its unsuitable quality. The diet should contain an increased proportion of vegetable foods, especially those which contain much cellulose and organic acids. Fresh or dried fruit should be taken three times a day, and green vegetables or salad should be eaten at lunch and dinner. Stewed prunes taken at breakfast, the number being regulated according to the degree of constipation, are especially valuable. Porridge and cream and wholemeal brown bread are also useful. Care should be taken that sufficient fluid is drunk; a glass of cold water taken on rising in the morning often helps the bowels to act after breakfast.

The majority of cases of constipation can be cured without drugs if proper treatment is instituted at a sufficiently early stage. In dyschezia purgatives are either absolutely useless or they only have an effect when fluid stools are produced, colic and toxic symptoms often resulting and a considerable quantity of fluid and nutritive material being wasted. In the treatment of diseases which are aggravated by co-existing constipation, purgatives should be regularly given. They are also useful for making the stools soft when straining at stool is accompanied by danger, as in patients with weak hearts or high blood-pressure. In colic constipation, when non-medical treatment proves insufficient, purgatives must also be used, but an effort should be made to dispense with them at the earliest possible moment. The stool produced by an aperient should be normal in size and consistence; the dose should be so regulated that one stool is passed every day and the desire to defæcate is felt immediately after breakfast. An infusion of senna pods in cold water is particularly useful, as the dose can be regulated from day to day by the patient; an attempt should be made at intervals to reduce the number used by one at a time, until finally none may be required. The aperient should cause no pain or discomfort, and should not irritate the intestinal mucous membrane sufficiently to lead to the appearance of mucus in the stools. If it is probable that the purgative will be required permanently, one such as aloes, cascara or senna should be chosen, which is likely to maintain its good effect without any increase in the dose being required.

In constipation due to a greedy colon the bulk of the fæces must be increased by the administration of some unirritating substance, such as liquid paraffin, agar-agar or coreine, which passes through the intestines without undergoing decomposition or absorption. These preparations are valuable when the fæces are hard and dry; they are therefore useful in other varieties of constipation besides that due to a greedy colon, as fæces always become hard and dry as a result of their abnormal retention in the bowel. In dyschezia the soft stools which result from their use are expelled with less difficulty than ordinary fæces. From 1 drachm to 1 ounce of paraffin or double the dose of a plain 50 per cent. paraffin emulsion should be taken immediately after one, two, or three meals every day. One drachm of agar-

agar or coreine, which absorbs water to form a bulky gelatinous mass which becomes intimately mixed with the fæces, is taken with one or more meals in addition to or as a substitute for paraffin.

The majority of cases of moderately severe constipation are more or less cumulative, excess of fæces being always present in the large intestines. It is therefore necessary that the colon should be completely evacuated before other methods of treatment are adopted. This can best be done by washing the colon out with a pint and a half or two pints of warm water run into it from a douche can at low pressure through a tube inserted just beyond the anal canal.

It is essential in treating dyschezia to keep the rectum and pelvic colon empty, so that they may in time regain their normal tone and contractile power. This can be accomplished by the use of enemata of glycerine every morning, but only if a prolonged attempt to defæcate naturally has proved unsuccessful. The strength of the enemata should be gradually reduced by replacing a drachm of the glycerine by water every other day until only water is used. As a rule the normal defæcation reflex and with it the tone and contractile power of the rectum slowly return.

When dyschezia is due to inability of the pelvic colon to empty its contents into the rectum, six ounces of paraffin should be injected on going to bed and retained during the night; the bowels are then generally opened without difficulty in the morning. If, however, they fail to act, a plain water enema should be given.

When the sphincter ani is in a condition of spasm as a result of inflamed hæmorrhoids or an anal ulcer, or when the anal canal is congenitally too narrow or a stricture has followed an operation for hæmorrhoids, complete relief can be obtained by dilating the passage by means of diathermy applied locally through a conical electrode.

Regular exercise in the open air is a valuable means of preventing constipation, especially in individuals who follow a sedentary occupation. When any of the voluntary muscles of defæcation are weak, considerable benefit can be gained by the performance of remedial exercises every morning and evening. Special attention should be devoted to the levator ani muscles—especially in women in whom the pelvic floor has been injured during parturition, and in cases in which there is any tendency to prolapse on straining at stool (*see* p. 729). Stasis in the proximal part of the colon is often benefitted by massage applied directly to the affected part. Its efficacy is greatly increased if the first treatment is given during an X-Ray examination, as the masseur can then see the exact position of the colon and can find what manipulations have most effect upon it.

DIARRHOEA

Definition.—Diarrhœa is a condition in which fluid stools are passed. Defæcation generally occurs several times in the day, but mere frequency of defæcation is not diarrhœa, for this may even be associated with constipation. The bulk of fæces excreted in 24 hours is generally excessive, but this again is not an essential factor, as excessive fæces are occasionally formed when the passage through the alimentary canal is not abnormally rapid.

The one essential factor in diarrhœa is the abnormally rapid passage of the food residue through the alimentary canal.

Ætiology.—1. **EXCESSIVE STIMULATION OF MOTOR ACTIVITY.**—The most common cause of diarrhœa is the presence in the food of excess of the mechanical and chemical stimulants of intestinal activity. Thus over-indulgence in green vegetables, salads, and still more frequently fruit, is a familiar cause. Chemical irritants may also be swallowed in decomposing food, as in some cases of fish and meat poisoning, but food may also cause diarrhœa by giving rise to a bacterial infection of the intestine. Diarrhœa very frequently results from the habit of taking aperients, either in excess of what is required for the correction of chronic constipation, or even when the bowels left to themselves would act quite normally. Thus many of the symptoms often ascribed to constipation are really due to the diarrhœa caused by purgatives, as it results in the absorption of excess of poisons from the too fluid fœces.

Chronic diarrhœa is a common sequel of the acute diarrhœa following infection with any pathogenic organism which gains access to the intestines in contaminated food or water, and it may follow acute general infections such as influenza. In both cases the subsequent diarrhœa may be gastro-genous (*vide infra*) and due to the achlorhydria resulting from gastritis caused by the infection and not the direct result of bowel infection. In some cases the infection is derived from a septic focus in the mouth, nose or pharynx, and in rare cases chronic appendicitis is the source of a chronic infection of the colon. Some infective bacteria, such as the parenteric group, act chiefly on carbohydrates and may lead to excessive fermentation. Others, such as streptococci and various anaerobes, act on proteins and lead to putrefactive diarrhœa. Severe intestinal carbohydrate dyspepsia (p. 630) may give rise to chronic diarrhœa or alternating constipation and diarrhœa, which is, however, rarely severe, and deficient digestion of proteins, resulting from either gastric or pancreatic insufficiency, may lead to a non-infective putrefactive diarrhœa. Deficient digestion of fat owing to pancreatic insufficiency or obstruction to the outflow of pancreatic juice in obstructive jaundice occasionally leads to fatty diarrhœa, which must be distinguished from chylous diarrhœa in which excess of fatty acids and soaps are passed owing to obstruction of the lacteals by disease of the mesenteric glands or to the presence of sprue or cœliac disease.

Diarrhœa is often gastric in origin. This *gastrogenous diarrhœa* may occur when the gastric juice is deficient or absent. An abnormal number of organisms reaches the intestines in these circumstances, as the partial protection afforded by the bactericidal action of the hydrochloric acid in the stomach is lost. As in addition to the digestion of meat in the stomach the connective tissue of meat and the cellulose of vegetables are normally softened by the hydrochloric acid of the gastric juice, undigested lumps of meat and fragments of vegetable leave the stomach and pass through the small intestine to the colon, where they are liable to undergo bacterial decomposition. The irritation of the mucous membrane of the intestines by the insufficiently divided fragments of food and by the products of bacterial decomposition leads to diarrhœa, which may become aggravated by secondary enteritis or entero-colitis if the irritation is sufficiently intense or prolonged. Similar gastrogenous diarrhœa may occur after the performance of a gastro-

jejunostomy, the food leaving the stomach with such rapidity that the intestines are overwhelmed with undigested and irritating food.

Lastly, chemical stimulants to intestinal activity may be produced in the body and excreted into the colon; this is the cause of diarrhœa in uræmia, Graves' disease and septicæmia.

2. OVER-EXCITABILITY OF THE NEURO-MUSCULAR MECHANISM WHICH CONTROLS THE INTESTINAL MOVEMENTS.—(a) *Lienteric or post-prandial diarrhœa*.—Under normal conditions the entry of food into the empty stomach gives rise to a gastro-colic reflex, which is the chief stimulus to the movements of the colon. In most individuals this is only followed by defæcation after breakfast, as the pelvic colon is then full, and the sudden passage of fæces from it into the rectum gives rise to the call to defæcation. Sometimes the gastro-colic reflex is abnormally active. This may only manifest itself after breakfast; a formed stool is passed first, but in the course of the next half-hour or hour one or more loose stools are passed in addition. In severer cases the bowels are also opened after dinner and less frequently after lunch, the stools again being often soft or fluid.

(b) *Nervous diarrhœa*.—It is not uncommon for a fright to result in the immediate passage of a semi-fluid stool. In some patients, who are often not otherwise neurotic, attacks of diarrhœa occur whenever they are in any place where it would be awkward for them to relieve themselves: when this has once happened, it is likely to recur under similar circumstances, largely owing to fear that it will do so. Lienteric and nervous diarrhœa are often associated together, a patient suffering from the former being particularly likely to feel an urgent desire to defæcate if he is at a dinner-party or in a railway carriage without a lavatory.

Diarrhœa, whatever its cause may be, tends to be worse after meals, especially breakfast, and it is occasionally also influenced by nervousness; it is important, therefore, to exclude some other primary cause before diagnosing a case as one of pure lienteric or pure nervous diarrhœa.

(c) *Irritable colon*.—When the mucous membrane of the colon is inflamed or ulcerated, any mechanical or chemical stimulant is likely to produce an excessive reflex response, so that the diarrhœa which is probably already present is aggravated. Apart from this, many people, who have lived in the tropics and have suffered there from dysentery or from diarrhœa due to some less defined cause, continue to be liable to diarrhœa for many years after their return to a temperate climate.

3. ORGANIC INTESTINAL DISEASE.—(a) *Enteritis*.—The profuse, watery diarrhœa of acute food poisoning and acute infections such as abdominal influenza and septicæmia is a result of acute enteritis, which is generally accompanied by acute gastritis, especially if vomiting is present, but the colon is often spared. The irritating products of the excessive bacterial activity resulting from the stasis in organic obstruction of the small intestine give rise to enteritis; consequently diarrhœa is almost always present in chronic small intestine obstruction. The contents of the stomach pass so rapidly through the small intestine that they are quite fluid and very bulky when they reach the cæcum; they consequently act as an enema and are almost immediately evacuated, even if the colon remains quite healthy.

(b) *Colitis*.—Diarrhœa is a constant symptom of acute inflammation of the colon, except in the rare cases in which it is confined to the proximal

part. Thus it is always present in ulcerative colitis and bacillary dysentery, in which the disease begins and remains longest in the pelvic colon and rectum, but it may be absent in mild cases of amœbic dysentery in which the cæcum alone is involved. Diarrhœa may occur in carcinoma of the colon, especially the distal part, before the lumen has been narrowed sufficiently to lead to fecal retention. The diarrhœa in these conditions is due to irritation of the bowel by the products of bacterial decomposition of the albuminous exudate of the diseased parts, and in colitis also to deficient absorption of fluid by the inflamed mucous membrane.

Symptoms.—The chief and often the only symptom of diarrhœa is the abnormally frequent passage of abnormal stools. In severe cases of diarrhœa discomfort or even pain is felt over the whole of the lower part of the abdomen for a short time before the bowels are opened. It may be followed by a sensation of soreness, but the abdomen is neither tender nor rigid, and warm applications generally relieve it. Occasionally severe colic occurs, which may be temporarily relieved each time the bowels are opened or flatus is passed. The passage of a large and watery stool is often followed by a feeling of exhaustion and faintness, which may be accompanied by sweating and coldness of the extremities and occasionally even by syncope.

In severe cases of acute diarrhœa, and in persistent cases of chronic diarrhœa, the nutrition suffers and the patient loses weight; sometimes an extreme degree of emaciation results. When the diarrhœa is associated with abnormal bacterial activity in the intestines, especially if this is of the putrefactive type, symptoms of intestinal intoxication may develop.

Diagnosis.—When a patient complains of diarrhœa, it is first necessary to ascertain whether the passage of feces through the intestines is really taking place with abnormal rapidity. Many people think that frequent defæcation, particularly if the stools are in part fluid, is sufficient evidence that diarrhœa is present, whereas this is by no means necessarily the case. The stools of every patient supposed to be suffering from diarrhœa should be examined; if they are of a uniform semi-solid or fluid consistence, true diarrhœa is probably present, whereas numerous stools, if they are small and solid, and fluid stools containing small solid fragments suggest a diagnosis of pseudo-diarrhœa. In a doubtful case, 2 or 3 charcoal lozenges should be given with some food immediately after the bowels have been opened in the morning; each stool is now examined, and the time which elapses before black feces are passed is noted. If charcoal is seen in the stools within 12 hours, true diarrhœa is present; if in less than 4 hours, the small intestine must be involved as well as the colon. If no charcoal appears within 48 hours, constipation and not diarrhœa is present. A series of X-Ray examinations after a barium meal affords a more accurate method of determining the rate of passage through the alimentary canal, and it has the advantage of showing in what part of the bowel the rate is excessive. In small intestine diarrhœa the head of the opaque meal may reach the cæcum within an hour or two; when the colon alone is involved, it arrives after the usual interval of 3 or 4 hours.

The most common cause of pseudo-diarrhœa is dyschezia; although the rectum is never properly emptied, the patient may feel a constant desire to open his bowels, and as a result of his efforts a very small quantity of hard feces may be passed. If, as is often the case, the constant presence of feces

in the rectum gives rise to catarrhal proctitis, more or less mucus is passed in addition. In slight cases there may be nothing more than a thin layer of mucus over the hard lumps of faeces; in severer cases a larger quantity of fluid mucus, which is often stained brown, is passed either alone or with hard particles of faeces. In all such cases the discovery of solid faeces in the rectum immediately after the bowels have been opened should remove any further doubt as to the diagnosis. A growth of the rectum or pelvic colon, and less frequently a growth in other parts of the colon, though rarely on the proximal side of the splenic flexure, may lead to pseudo-diarrhoea, faeces being retained above the growth, whilst the serous and often blood-stained exudation from its surface and mucus produced by the irritant action of the exudation of the mucous membrane below it are passed at more or less frequent intervals, so that the patient regards himself as suffering from diarrhoea. The character of the stools should at once make it obvious that further examinations by means of the sigmoidoscope and with the X-Rays after a barium meal and a barium enema are required, even if nothing abnormal is felt in the abdomen or on rectal examination.

When it is known that genuine diarrhoea is present, it is next necessary to determine whether it is due to a functional or an organic cause. The history is often a great help: lenteric or nervous diarrhoea of long duration is generally gastrogenous. A very acute onset suggests that the cause is some toxic or infective agent, whereas a more gradual onset of chronic diarrhoea in a middle-aged individual, who has hitherto been regular or constipated, suggests the presence of a growth. A careful abdominal and rectal examination should be made in every case; the former may reveal the presence of a tumour or an abnormally dilated or contracted condition of the colon; by means of the latter the existence of ulcerative colitis may be recognised, as well as the presence of a growth in the rectum or pelvic colon. In doubtful cases a sigmoidoscopic examination should also be made before deciding that the diarrhoea is functional in origin, as the mucous membrane of the accessible part of the colon is almost always involved when diarrhoea is due to some form of colitis.

The examination of the stools is of the greatest importance, as it gives valuable indications for treatment as well as helping in diagnosis. In small intestine diarrhoea the stools are watery, whereas in colonic diarrhoea they are unformed but not fluid. The presence of mucus, blood or pus indicates either some form of colitis or a growth. The presence of excess of starch, meat fibres or fat indicates a small intestine diarrhoea. Excess of undigested starch is found on microscopical examination in fermentative diarrhoea, and of striated muscle fibres in putrefactive diarrhoea. The faeces are often frothy and have an acid smell and reaction when fermentation is excessive; they are alkaline and have a putrefactive odour when excessive putrefaction is present.

The stools passed when fat is insufficiently digested or absorbed are easily recognised by their pale colour and enormous bulk. If the excess is in the form of neutral fat, the stools are oily (*fatty diarrhoea*), and pancreatic insufficiency can be diagnosed; on giving a fat-free diet, excess of striated meat fibres is still present. This condition is, however, very rare in the absence of jaundice caused by obstruction of the common bile duct. More frequently most of the fat is present as fatty acid and soaps (*chylous diarrhoea*),

showing that pancreatic digestion is normal, but that absorption is deficient owing to obstruction of the lacteals by tuberculous, simple inflammatory or secondary malignant disease of the mesenteric glands, or to the presence of cœliac disease in children, or sprue in adults who have been, sometimes many years earlier, in the tropics. In such cases the stools become perfectly normal on a fat-free diet, the digestion of meat and vegetable food being unaffected. Almost all the calcium in the food combines with fatty acid to form calcium soap in this condition; the blood calcium is consequently diminished, and tetany may result. In children growth is greatly impaired, and the long bones are soft and may bend, with the production of various deformities.

A bacteriological examination should always be made, in the hope that the nature of any infection which is present may be discovered.

Prognosis.—If thorough treatment is instituted from the onset, the prognosis of diarrhœa is good, unless it is due to some serious organic disease. If, however, it is neglected, strict treatment must be continued for a prolonged period in order to be successful. This is particularly the case when the diarrhœa is infective in origin.

The tendency to lenteric and nervous diarrhœa often remains throughout life, though considerable improvement and even a cure can result from treatment. Unlike other forms of diarrhœa, they rarely affect the general health, and are chiefly troublesome on account of the inconvenience they cause.

Treatment.—*Acute Diarrhœa.*—The patient should be kept warm and at rest in bed until the attack has completely subsided. If it is due to food poisoning and he is seen within 12 hours of the onset, he should be given from $\frac{1}{2}$ to 1 ounce of castor oil to clear the irritant material out of the small as well as the large intestine, unless the diarrhœa is so severe that it appears probable that this has already occurred. No food should be given for 24 hours, or even longer in severe cases, but the patient may drink as much water as he likes. Arrowroot made with water should then be given, but nothing else until the diarrhœa has ceased. Milk, junket, bread and butter, and milk puddings are next allowed, after which a gradual return should be made to an ordinary diet, the speed with which this is done depending on the severity of the case. The only drugs which are of real use in acute diarrhœa are opium and its alkaloids. If the diarrhœa shows no signs of abating after 24 hours, some codeine should be given, the dose being regulated according to the severity of the diarrhœa and the general condition of the patient, but sufficient must be given to stop the diarrhœa in 48 hours. If the diarrhœa is accompanied by vomiting, a test-meal should be given about a month later, even in the absence of all symptoms, as the accompanying acute gastritis may have led to achlorhydria, which is likely to give rise to chronic diarrhœa or other trouble later unless the underlying chronic gastritis is overcome.

Chronic diarrhœa.—In all cases of chronic diarrhœa, recovery occurs most rapidly if the patient remains in bed during the first few days of treatment. In many instances, diarrhœa, which may have been present for months, disappears in a few days, and the patient may even become constipated. Unless, however, other treatment is instituted, the diarrhœa is very likely to return as soon as he gets up again. As the improvement which results from staying in bed is due in part to the rest and in part to warmth, it is important for the patient to avoid over-exertion and to keep his abdomen

warm by means of a woollen binder for a considerable period after the symptoms have disappeared. Exposure to cold should be avoided as much as possible, and if the patient feels chilled at any time he should have a hot bath and go to bed at once; by these means he is likely to prevent a recurrence. Patients who have recently suffered from chronic diarrhœa should never go to the tropics, and they should even avoid visiting the southern parts of Europe, as a slight intestinal attack from bad food is likely to have much more serious results with them than in an individual who has not before suffered from any intestinal disorder.

The successful treatment of chronic diarrhœa depends upon the recognition of its cause. The treatment of diarrhœa which is secondary to organic disease of the intestines, such as colitis and cancer, is considered elsewhere.

1. EXCESSIVE STIMULATION OF THE INTESTINAL MOVEMENTS.—Whatever the actual cause of the diarrhœa, it is important to avoid anything which could produce mechanical irritation of the colon. The food should be thoroughly chewed, and anything, such as new bread, cheese and tough meat, which is difficult to break up completely, should not be eaten. The patient must avoid all raw vegetables in salads and pickles, and cooked green vegetables are only allowed as purées. The pips and skins of fruit, whether raw, cooked or in jam, and currants, raisins and lemon peel in puddings and cakes must be avoided.

For the treatment of *fermentative diarrhœa*, *vide* Intestinal Carbohydrate Dyspepsia (p. 631). A lacto-vegetarian diet is most suitable for *putrefactive diarrhœa*. A teaspoonful of a fresh liquid culture of *B. acidophilus* should be given three times a day between meals. No meat should be allowed until the diarrhœa has ceased for 4 weeks, and high game and over-ripe cheese should be permanently avoided.

Fatty and chylous diarrhœa stops at once on a fat-free diet. In severe cases, in which obstruction of the lacteals is present, it may be necessary for the patient to continue with this diet for the rest of his life.

Gastrogenous diarrhœa rapidly improves on the diet already described as suitable for putrefactive diarrhœa, but a relapse is certain to follow a return to an ordinary diet unless the achlorhydric gastritis is properly treated (*vide* p. 577).

2. NERVOUS AND DYSENTERIC DIARRHŒA.—Nervous diarrhœa is often completely uninfluenced by diet, but drugs, which diminish the activity of the gastro-colic reflex either peripherally or centrally, are very effective. A mixture containing 5 grains of potassium bromide and 5 minims of tincture of belladonna taken immediately before meals is all that is required in mild cases; in severer cases a small dose of codeine should be added. The exact dose of each drug must be varied to suit each patient, as different individuals react very differently to these drugs, especially to belladonna. When the diarrhœa has been completely controlled, the quantity of each drug should be gradually reduced; then the doses before lunch and dinner, and finally that before breakfast, can be discontinued. In some cases it is advisable to allow the patient to have the medicine or a pill containing belladonna and codeine always with him, so that he can take a dose before going to a dinner-party or on any other occasion when he fears that he will have diarrhœa. He soon learns to trust so thoroughly in his pill that it probably acts more

by suggestion than in any other way, and the dose can accordingly be progressively reduced until it is infinitesimal.

As in many cases of diarrhœa due to other causes the bowels act most frequently after meals, the treatment just described is often of use in conjunction with that required for the primary condition.

ARTHUR F. HURST.

EPIDEMIC DIARRHŒA IN CHILDREN

Synonyms.—Summer Diarrhœa ; Infective or Infectious Diarrhœa ; Acute Gastro-Intestinal Infection ; Acute Ileo-Colitis ; Cholera Infantum.

The form of diarrhœa here spoken of is one of the chief scourges of infant life, though certainly much less common than formerly. It prevails epidemically in the third quarter of the year, although sporadic cases may be met with at any time, and in hot seasons may become widespread, especially in large towns. It chiefly affects children below the age of 5, but is most fatal in the first year. Boys are more susceptible than girls.

Ætiology.—It is generally agreed that the disease is caused by infection with micro-organisms ; but in spite of much research the bacteriology is by no means clear. It would appear that all cases are not due to the same organism, and amongst those which have been isolated from the stools in different epidemics are the *Proteus vulgaris*, the *Bacillus coli*, streptococci, the *B. enteritidis*, Morgan's bacillus, members of the para-typhoid group, and various strains of dysentery bacilli. Any of these, or several of them in combination, seem to be capable of inducing the affection, given the predisposing conditions. Of the latter by far the most important is a sustained high temperature (60° F.) of the air and, particularly, of the soil. As was pointed out long ago by Ballard, it is when the temperature recorded by the four-foot earth thermometer reaches 56° F. that cases begin to occur. Such a temperature probably provides the conditions necessary for the growth of the infecting organism.

Next in importance as an ætiological factor must be put the influence of unhygienic surroundings, such as dirt, overcrowding, a contaminated milk supply, and want of cleanliness in feeding utensils. The infection is probably often conveyed by dust, and flies may act as carriers.

Any digestive derangement in the child may predispose to infection, and bottle-fed infants are specially liable. The disease appears to be to some degree contagious, and if introduced into a ward is apt to spread to unaffected infants. The influence of age and sex have already been referred to.

Pathology.—The changes found after death may be surprisingly slight, considering the severity of the disease, and vary materially in different cases and epidemics. As a rule the mucous membrane of the stomach and intestines is in a condition of "mucous catarrh." There may also be areas of congestion, with here and there small petechial hæmorrhages. The lymphoid tissue of the alimentary canal is often swollen, and in severe and protracted cases the solitary follicles in the colon and lower ileum may exhibit superficial ulceration.

Other organs, such as the liver and kidneys, show fatty or parenchymatous degeneration, whilst the lungs are often congested and œdematous, with, in protracted cases, patches of broncho-pneumonia in the lower lobes.

Symptoms.—The clinical picture is often very complicated, and if it is to be understood it is essential to realise that the disease is a general infection and not merely a disorder of the alimentary canal. The supervention of secondary "food intoxications," acidosis or nephritis, with their own clinical manifestations, tend still further to perplex the observer and make it impossible for him to decide to what extent the symptoms are due to the primary infection or to these secondary developments.

The disease may start insidiously, with a gradually increasing diarrhœa; or the onset may be abrupt, with a rapid rise of temperature and early prostration. The diarrhœa is not necessarily a pronounced feature, and the worst cases are often those with fewest stools. The character of the motions varies; but in the early stage they are usually green, slimy and ill-digested, becoming dark and watery later. In the choleraic cases they are of the profuse "rice-water" type. When the colon is affected, visible mucus and blood may be passed with much straining. The discharges are usually attended by colicky pain and the passage of flatus. Vomiting is generally present at the onset, but varies greatly in amount. The temperature is always elevated at some period of the disease, but the height, duration and course of the pyrexia are very inconstant. Hyperpyrexia may supervene towards the close in fatal cases. Prostration and circulatory failure are early features, and are shown by depression of the fontanelle, pallor, pinched features, an inelastic skin and coldness of the extremities. Where "intoxication" is a factor, consciousness becomes impaired, and the infant passes into a state of stupor, with intervals of restlessness, which may result in complete coma, sometimes terminating in convulsions. If acidosis is present, the respiration may show the characters of "air-hunger."

The urine is scanty, highly acid and contains a little albumin and a few hyaline casts. Acetone bodies may be present.

Course.—The course of the disease varies greatly. In the severest cases, especially those of the choleraic type, death may ensue within a few hours of the first onset of symptoms. In the milder forms the acute symptoms last for 2 or 3 days, and then gradually the prostration passes off and the stools assume a normal character. Only too often, however, the improvement is but partial, and the child lapses into a marasmic condition, with continued looseness of the bowels, from which recovery may only take place gradually as cooler weather arrives. In all cases relapses, brought on either by re-infection, by meteorological conditions, or by injudicious feeding, are extremely common and apt to prove fatal.

In children above the age of 2 the disease usually assumes a milder form—prostration is not so severe and the range of temperature lower. Vomiting, also, is a less prominent symptom than in infants. Complete recovery is more frequent, and relapses and the continuance of the disease in a chronic form are rare.

In the special type of the disease commonly spoken of as "cholera infantum" the invasion is always abrupt, with a rise of temperature, followed by profuse vomiting and purging. Prostration is marked from the outset. The stools are frequent and large, and though greenish and slimy at first quickly become watery, colourless and almost odourless. Thirst is intense, and the infant rapidly becomes shrunken and dehydrated. Death usually ensues in a few hours, and is commonly attended by hyperpyrexia.

Diagnosis.—The diagnosis has to be made from simple non-infective diarrhoea. At first the differentiation may be impossible, but continued high temperature, early prostration and failure of rapid improvement on stopping food point to an infective origin. Epidemic prevalence is also in favour of the more severe variety. The nervous symptoms may simulate those of meningitis, but in case of doubt a lumbar puncture will determine the diagnosis. Very acute cases, in which the colon is much involved, may resemble intussusception, but in the latter the onset is more dramatically sudden, the vomiting, collapse and passage of blood greater, and fever less, whilst in epidemic diarrhoea abdominal rigidity and tumour are absent.

Prognosis.—It is impossible to give any estimate of the fatality of diarrhoea, as it depends greatly on the type of the disease, and on the age, general condition and surroundings of the child, besides varying greatly in different epidemics. The younger the infant, and the poorer its general nutrition, the worse is the outlook. The existence of rickets also greatly aggravates the danger. The frequency of the stools is of less importance in estimating the chance of recovery in any given case than the amount of prostration and the degree of inelasticity in the skin. Cases with prolonged high temperature and those of the choleraic type usually do badly. Persistence of vomiting also is a bad sign.

Treatment.—Unfortunately there is no specific treatment, and the principles to be aimed at are : (1) to stop the infection ; (2) to eliminate and neutralise toxins ; (3) to combat collapse ; (4) to arrest the vomiting and purging.

1. In attempting to stop further infection, general hygienic measures are of great importance. Whenever it is possible, the child should be removed from a town, and isolated in a large, airy and well-ventilated room. Napkins should be removed and disinfected as soon as they are soiled, and the greatest cleanliness should be observed in regard to the feeding utensils and the nurse's hands.

If the case comes under observation early, an initial purge of castor oil or, if there be much vomiting, of calomel should be given to clear away decomposed matter from the bowel. Milk, which is the vehicle of infection, should at once be stopped, and for the first day or two the diet should be limited to plain water, barley water, weak tea, rice-water, 7½ per cent. glucose, or weak broths, all of which may be given freely.

2. In order to favour the elimination of toxins, the action of the skin and kidneys should be promoted as much as possible. To this end, if the skin be very inelastic, tepid packs are useful, and these may be continued, if necessary, for several hours on end. If the urine be scanty, a few drops of sweet spirits of nitre may be administered, and water should be given freely.

In the early stages of the disease no attempt should be made to arrest the diarrhoea entirely, as the retention of poisons would then be favoured. In addition to the initial purge, irrigation of the colon is a valuable aid in removing toxic material. Normal saline administered at a temperature of 100° F. through a rectal tube or large-sized red rubber catheter is the best solution to employ.

The direct neutralisation of the toxins is, unfortunately, not at present

practicable, as no efficient antitoxic serum for the disease has yet been found.

3. Collapse has to be obviated by saline infusion and the use of stimulants. Four ounces of normal saline may be injected under the skin of the flank every 6 hours. In very severe cases whole-blood transfusion may save life.

Of stimulants, one of the best is alcohol. Ten to 15 drops of brandy may be given in a little water every 3 or 4 hours, or oftener; it should not be added to the feeds. Camphor is also useful, and is best given dissolved in olive oil (1 in 15 or 1 in 30). Five minims of this solution may be injected under the skin as often as is thought necessary, or a few drops of spirits of camphor may be given by the mouth. If the collapse is extreme, recourse may be had to the mustard bath.

4. The arrest of the vomiting and especially of the diarrhœa is really a secondary object of treatment. For the vomiting, lavage of the stomach is the best treatment, particularly in the early stages, and a poultice may be applied to the epigastrium. Drugs are of little help, but small repeated doses of calomel (e.g. $\frac{1}{4}$ grain every hour for six doses) are sometimes useful. Chlore-tone in 1-grain doses may also be used cautiously. Iced champagne diluted with an equal quantity of soda water is sometimes of service.

As has already been pointed out, no active steps should be taken to arrest the diarrhœa at the onset. If it continues, however, and seems to be contributing to the exhaustion, one may try to reduce the frequency of the stools. In the early stages, small repeated doses of castor oil are useful for this purpose, and later, when the tongue is clean, bismuth, chalk, catechu and other astringents, as in the case of simple diarrhœa, may be used. A powder composed of 5 grains of bismuth carbonate, with $\frac{1}{4}$ th grain each of Dover's powder and calomel, is also a frequent prescription at this stage. Opium should not, however, be given at the outset, and it is best withheld so long as prostration is marked and the temperature high. When prescribed, it may be given in the form of the tincture in the proportion of 1 minim for every year of the child's age. It is specially indicated when the motions are frequent and attended by much colic and tenesmus. In cases of the choleraic type, with much vomiting and profuse purging, morphine may be given hypodermically with great advantage. The dose for a child of 1 year is $\frac{1}{50}$ th grain, with which $\frac{1}{600}$ th grain of atropine may be combined. This may be repeated in an hour if the symptoms have not abated.

"Intestinal antiseptics" are of little help, and may easily be injurious. The best are salicylate of bismuth, salol and resorcin. If the stools are very watery, nitrate of silver is the most powerful astringent.

After the acuter symptoms have passed off one must return very gradually to ordinary diet. Milk should be given at first malted or fully peptonised and freely diluted with lime water, or condensed or desiccated milk, or one of the patent foods may be used in place of it. A feed may be given every 4 hours, and water between if the child is thirsty. Any return of the vomiting or diarrhœa must be the signal for again giving up milk in any form. During convalescence change of air and mild iron tonics are of service in restoring the child to complete health. Relapses, which are frequent, must be guarded against with the greatest care.

HILL DIARRHŒA

Definition.—A peculiar form of gastro-intestinal derangement occurring in Europeans living at high altitudes in India, Ceylon and elsewhere during the hot season, characterised by dyspeptic symptoms, abdominal flatulence and the passage of pale-coloured or white, frothy, fluid stools early in the morning.

Ætiology.—The condition occurs in the Himalayan hill stations of India and the highlands of Ceylon, Europe and South America, at elevations of 6000 feet or over. Europeans of both sexes and all ages are liable, and in some years the condition has affected a large portion of the hill population, as in the Simla epidemic of 1880. The cause has been variously attributed to the mica content of the drinking water, to its bacterial contamination, as well as to a physiological breakdown of the gastro-intestine under conditions of low barometric pressure and high humidity: the latter view is probably correct.

Pathology.—Little is known either of the clinical pathology or morbid anatomy of the disease, the nature of which will remain obscure until it has been investigated along biochemical lines, such as has recently been done in sprue.

Symptoms.—The symptoms are flatulence and abdominal distension associated with morning diarrhœa. Defæcation is urgent and generally first occurs about 5 a.m.; subsequently the bowels may be opened four or five times before noon, after which the patient is comfortable. The stools are copious, fluid, pale-coloured or white, frothy, and generally not objectionable in odour. Fat analyses, unfortunately, have not been made. Often the condition is transient, but if it persists considerable loss of weight may ensue.

Prognosis.—This is generally quite good; the only danger is that the condition may develop into sprue, and Rogers states that 20 per cent. of his Calcutta cases commenced with hill diarrhœa.

Treatment.—Until more is known regarding the exact nature of the gastro-intestinal breakdown treatment must remain empirical. Rest, warm clothing and milk diet are generally advised, and probably a high protein, low fat, low carbohydrate diet, such as sprulac, would prove valuable. Dilute hydrochloric acid in 1 drachm doses after food may be tried, and pepsin has also been advocated. Crombie used to give a drachm of liq. hydrarg. perchlor. 15 minutes after food. Should these measures not suffice the patient must return to the plains.

CŒLIAC DISEASE

Synonyms.—This disease was first described by Gee in 1888 under the title of "The Cœliac Affection." Cheadle redescribed it in 1903 as "Achoia," and Herter in 1908 as "Intestinal Infantilism." It is sometimes spoken of in America as "Chronic Intestinal Indigestion," but in this country the term "Cœliac Disease" is now generally applied to it.

Definition.—A wasting disease of childhood characterised by the passage of large, pale, offensive stools which contain an excess of split fat, and leading to emaciation and arrest of growth; various complications due to avitaminosis may be superadded.

Ætiology.—The cause is unknown. There is no hereditary element; girls are more susceptible than boys, and no social class is exempt. The disease appears to be rarer in the Latin countries than in the Anglo-Saxon and Scandinavian.

Pathology.—There is no characteristic morbid anatomy, the post-mortem changes being attributable to inanition or to intercurrent disease from secondary infection. The bones tend to show osteoporosis. On biochemical investigation the blood is found to be poor in calcium. The essential pathogeny of the disease appears to be a failure in fat and carbohydrate absorption of obscure causation. The ordinary changes of enteritis are not found.

Symptoms.—The disease begins insidiously between the ninth month and the end of the second year. The child loses appetite, fails to thrive, and has slight diarrhœa. Soon the characteristic stools appear. They are large, but not necessarily frequent, pale, extremely offensive and sometimes frothy and fermenting. On chemical examination they contain from 40 to 60 per cent. of split fat instead of the normal 25 per cent., but the amount of unsplit fat present is not altered. Meanwhile the emaciation progresses, the face being least affected by it and the buttocks most. The abdomen, by contrast, is prominent, doughy and distended, and may sometimes contain a little free fluid. Along with these physical signs there is a change in mentality. The child is often remarkably precocious, but is irritable, hysterical and "difficult," especially during the exacerbations. There is frequently a profound anorexia, and muscular weakness may be extreme.

Complications.—Various deficiency symptoms are apt to appear as the result of avitaminosis induced either by impaired fat absorption or by the character of the diet which treatment demands. Rickets may show itself either early, or, after the age of 7, in the "late" form, with genu valgum as its main sign. Symptoms such as œdema and absence of reflexes may suggest beriberi and have been attributed to deficiency of vitamin B. Scurvy is not uncommon, and attacks of tetany may occur in association with the low blood calcium.

Diagnosis.—At the outset the disease may be impossible to recognise, but when the characteristic stools appear diagnosis is easy. Arrest of growth is of great diagnostic value. The distended abdomen may suggest tuberculosis, especially if slight ascites is present. Cœliac disease presents many points of resemblance to sprue, but the latter is very rare in childhood, and in cœliac disease the blood shows a secondary anæmia and not the megalocytic type characteristic of sprue.

Course and Prognosis.—The disease runs a prolonged course with many ups and downs and is peculiarly prone to relapse. It may last into adult life (cases of "non-tropical sprue" may be examples of unrecovered cœliac disease) but usually tends to recovery before puberty. The mortality may be put down at about 10 per cent., and death, when it occurs, is usually due to intercurrent disease. During the active phases of the disease growth is arrested, and even after recovery the patient may be permanently stunted (intestinal infantilism).

Treatment.—Apart from general hygienic measures treatment is essentially dietetic. A diet high in protein, low in fat, and with no carbohydrate (at the outset at least) is the ideal to aim at. It may consist at first of a dried "protein" milk with the addition of underdone scraped meat, white of egg,

broth, jellies, etc. Later, small quantities of fat in the form of bacon and butter are added with carbohydrate mainly in dextrinised form (Mellin's Food, grape-nuts, rusks, crisp toast, etc.). Over-ripe bananas often have a beneficial effect. Care must be taken to supply the necessary vitamins in order to ward off complications. Vitamin A may be given as Carotene; B, as Yeast extract; C, as Orange juice; and D, as Ergosterol. A small dose of castor oil should be administered when abdominal distension is troublesome; otherwise there is no indication for drugs. Exposure to ultra-violet light helps to prevent the development of rickets.

ROBERT HUTCHISON.

SPRUE

Synonyms.—Cochin-China Diarrhœa; Psilosis; Ceylon Sore Mouth, etc.

Definition.—Sprue is a disease of unknown ætiology involving the gastro-intestinal tract, characterised by defects in gastric secretion and inability to absorb adequately fat, glucose and calcium. Typically there is an apyrexial, morning diarrhœa with bulky, pale, gaseous, fatty stools, inflammatory lesions of the tongue and buccal mucosa, megalocytic anæmia, asthenia and wasting.

Ætiology.—The disease is mainly confined to the tropics and sub-tropics, being especially common in parts of India (Bombay), China and Cochin-China, also in Ceylon, Java, the Federated Malay States and Porto Rico in the West Indies. Adult Europeans and people of mixed European blood living in endemic areas are prone to infection: natives more rarely suffer. Both sexes are susceptible, but it rarely affects people under 20 years of age. A hot, damp climate, especially on the seaboard, favours its development, while certain bungalows enjoy an unsavoury reputation in this regard. Various theories have been suggested to explain its ætiology. The first infective agent was thought to be *Strongyloides intestinalis*. Later Ashford and others held it to be a moniliasis of the digestive tract due to *Monilia psilosis*, but the fungoid theory is now being generally abandoned. Scott considers that there is a metabolic disturbance, resulting in a decreased ionic calcium due to parathyroid involvement. The idea that it is a physiological breakdown in the tropics also has its adherents, but this does not explain latent sprue, which may first manifest itself 25 years after the patient has left the tropics. Elders regards sprue as a primary deficiency disease due to lack of vitamins A and B and amino acids, but the difficulty in accepting such a view is the epidemiological fact that sprue often affects the best fed people in the community. As in certain other megalocytic anæmias, evidence of an undoubted relationship between sprue and the vitamin B complex does exist, but in sprue it probably depends rather on inadequate preparation and absorption of some factor or factors in vitamin B than on a primary dietetic deficiency.

Pathology.—*Morbid Anatomy.*—At autopsy the essential lesions consist of an absence of fat, muscular wasting, an atrophic enteritis, an exceedingly small heart, general atrophy of the viscera consequent on malnutrition, a megaloblastic hyperplasia of the red marrow of variable intensity, and

inflammatory and atrophic changes in the tongue. The inflammatory lesions in both tongue and intestine may be patchy in distribution, transient in duration, and not always evident at autopsy.

Clinical Pathology.—The anæmia, which is by no means invariably present in the early stages, is generally megalocytic in type and exceptionally may be as intense as that seen in pernicious anæmia. The Price-Jones curve shows a displacement to the right and often broadening of the base, while the average corpuscular diameter exceeds 7.6 microns. The colour index is usually high. The blood picture shows numerous megalocytes associated with anisocytosis and poikilocytosis, and in the severer cases polychromasia, basophilic stippling, and occasional normoblasts and macro-normoblasts may be observed; megaloblasts are rare. Hypochlorhydria or achlorhydria is common, but 75 per cent. of cases respond to histamine by an increase in HCl secretion. Evidence is accumulating that the megalocytic anæmia has a gastrogenous origin due to defective production of Castle's factor. The total faecal fat is definitely increased (30 to 70 per cent.), but splitting is adequate. The glucose tolerance test frequently shows a flat or low curve, or one presenting a retarded rise due to malabsorption, while the blood calcium is decreased for the same reason. The blood bilirubin is rarely increased to the extent seen in pernicious anæmia. Malabsorption of fat accounts for the excessively fatty stool, while fermentation of glucose within the lumen of the bowel consequent on defective absorption underlies its acid and gaseous characteristics. The pallor of the stool is due to the transformation of stercobilin into colourless leucobilin. Functional tests of the liver and pancreas reveal no abnormality.

Symptoms.—The incubation period is unknown, but patients have occasionally developed sprue within a few months of arriving in an endemic area. Hill diarrhœa sometimes passes into sprue. Often the onset is insidious with (1) loss of energy, dyspepsia and flatulence; (2) rapid loss of weight; (3) sore tongue or buccal aphthæ; (4) simple diarrhœa. It may be months before the characteristic morning diarrhœa with the passage of several bulky, pale, acid, frothy stools reveals the true nature of the malady. Pyrexia is the rule, and frequently the temperature is subnormal. Once seen, the fully developed picture of sprue makes an indelible impression. Such a patient is asthenic, emaciated, mentally taciturn and often severely anæmic; the skin is parched, wrinkled and often pigmented over the forehead and malar eminences, while the nails are ridged and brittle; the tongue, which is invariably clean, may be patchily inflamed with prominent papillæ, ulcerated, atrophic or fissured, while the thin abdominal parietes scantily protect the attenuated coils of gas-distended bowel visible beneath. Physical examination also often reveals a decrease in the size of the liver dullness: this is partly attributable to atrophy and partly to intestinal distension. Hæmic murmurs may be heard over the heart, which is small, while both systolic and diastolic blood pressure is invariably lowered. On questioning such a patient he often complains of sore tongue and aphthous ulcers made worse by spiced and hot foods, of characteristic early morning stools, and of abdominal distension and intestinal flatulence generally most marked towards evening and often related to the carbohydrate intake. Œdema of the feet, cramps and tetany may occasionally be observed.

Complications.—Sprue is a disease peculiarly free from complications,

but pyrexia should always arouse suspicion that the case is running an abnormal course. Unlike pernicious anæmia, subacute combined degeneration of the cord is not encountered. Anal fissure and hæmorrhoids may develop, while tetany is met with in about 2 per cent. of the cases; intestinal perforation and pneumonia have occasionally been recorded. Intercurrent amebic infection is not common, despite the fact that some authors regard it as an ætiological factor in sprue.

Course.—Sprue is a very chronic disease, showing spontaneous remission and exacerbations, with a tendency to natural cure if the patient leaves the tropics. Death generally results from uncontrolled anæmia.

Diagnosis.—The well-established case presents little difficulty, but in the initial stages and in atypical cases considerable clinical experience may be required to make a diagnosis. Relapse cases, especially those following respiratory infections or chill, may only show megalocytic anæmia, intestinal symptoms sometimes being suppressed for weeks. The differential diagnosis includes pernicious anæmia, gastric carcinoma, gastro-colic fistula, tuberculous enteritis, Addison's disease, chronic pancreatitis and carcinoma of the pancreas. Biochemical and radiological investigations may be essential for their differentiation.

Prognosis.—This largely depends on obtaining the co-operation of the patient, though intercurrent diseases like arteriosclerosis and old age handicap recovery. Modern treatment has greatly increased the expectancy of life, and even in an endemic area like Bombay deaths are becoming rare.

Treatment.—The essentials of treatment are: (1) The institution of alimentary rest by appropriate dietary; (2) the treatment of megalocytic anæmia if present; (3) the reinforcement of demonstrable deficiencies by such means as HCl, calcium salts, etc. Both in the primary attack and during relapses these asthenic, poorly nourished patients must be put to bed for 5 to 8 weeks under conditions that ensure mental as well as physical rest, while in Europe warmth and the avoidance of chill are essential. (1)

Dietary.—Many different diets have been advocated, the best known being Manson's milk treatment. The feeds are given in small quantities 2-hourly, commencing with $3\frac{1}{2}$ and increasing gradually up to 7 pints daily. Van den Burg advocated large quantities of pulpy fruit free from acidity, coarse seeds and fibres; ripe bananas, bael fruit, papaya and strawberries are popular, the latter being particularly favoured in Europe. The red meat diet of Cantlie commenced with 2-ounce feeds of lean, minced, underdone steak, which were gradually increased until $1\frac{1}{2}$ to 2 lb. were taken daily. Recently, Fairley has introduced graded high protein, low fat, low carbohydrate diets, the ratios of the three fundamental food-stuffs being as 1.0 : 0.3 : 1.3 and the energy values varying from 600 to 3000 calories. Red meat is the main source of protein advocated, but more recently a defatted dried milk (sprulac), with similar food ratios has been produced for use in the tropics. These diets, biochemically controlled, and based on the defective utilisation of fat and carbohydrate in the small intestine are rapidly replacing all former dietetic treatments. (2) **Anæmia.**—The anæmia of sprue responds rapidly to the administration of commercial liver extract in adequate quantity, with a marked reticulocytosis, which reaches its maximum about the ninth day, and rapid blood restoration. Whole liver and ventriculin are also effective, but in the writers' opinion are not so

well tolerated from the alimentary standpoint. Daily injections of Hepatex P.A.F. during the first week are of value in severe cases in reinforcing liver extract *per os*, but when used alone have proved inadequate. Occasional cases respond dramatically to marmite (4 drachms daily), with a marked reticulocytosis and rapid blood restoration, but others just as constantly fail to respond and the anæmia increases. Blood transfusion may prove dangerous, especially when patients have been previously transfused; its only indication is to tide a dangerously anæmic patient over the latent period intervening between the administration and response to liver extract; it is now rarely necessary. Iron in adequate dosage is of occasional value, especially if the colour index be low or if the hæmoglobin curve remains stationary while the production of red cells is satisfactory. Commercial liver extract should be administered in a dosage equivalent to 1 to 1½ lb. of whole liver daily for the first month, after which the dose can generally be reduced. A maintenance dose equalling ½ lb. is necessary in certain cases, and should be adopted in all patients until the blood picture and average diameter of the corpuscle have returned to normal. (3) *Treatment of demonstrable deficiencies.*—The fractional test meal not infrequently reveals hypochlorhydria or achlorhydria, and under these circumstances ½ to 1 drachm of acid hydrochlor. dil. (B.P.) in orange juice after meals is indicated. Similarly if the blood calcium is lowered, calcium lactate in doses of 20 to 40 grains should be administered thrice daily, reinforced if there is tetany, or if Chvostek's or Trousseau's sign is present, by vitamin D. Scott and others have reported very favourably on calcium and parathyroid extract *per os* under similar circumstances. Pulv. Bataviæ Co. in doses of 1 drachm is also useful in this respect, as well as for stopping diarrhœa. The institution of high protein, low fat, low carbohydrate dietaries combined with liver extract therapy restores sprue patients to a normal state of health in the majority of cases, and it is now feasible to permit some of these to return to the tropics. On the other hand, it is never possible to predict with certainty that a given case is permanently cured, and great care should be taken to avoid chill, respiratory infections, and indiscretion of dietary, especially in respect to hot, spiced and sugary foods, alcohol and carbohydrate excesses. Sprue relapses may recur after many years of perfect health.

MUCO-MEMBRANOUS COLIC

Definition.—In neurotic individuals constipation is sometimes associated with the constant or intermittent passage of membranes of coagulated mucus and with attacks of pain, the condition being known as muco-membranous colic. This name is preferable to muco-membranous colitis, as no true inflammation of the colon is present.

Ætiology.—Muco-membranous colic was formerly a common condition in women of the educated classes, and was occasionally also observed in men. For no obvious reason its incidence has greatly diminished since the War, and well-marked cases are now rarely seen.

Pathology.—Two predisposing factors are invariably present—con-

stipation and an abnormally irritable nervous system. Retention of *faeces* in an individual with an abnormally irritable nervous system may result in reflex over-activity of the motor and secretory fibres of the colon, leading respectively to painful spasm and to excessive secretion of mucus. The former may occur alone; the resulting colospasm is analogous to pure spasmodic asthma, and, in contrast with muco-membranous colic, it is still quite common (p. 606). If the mucus is retained sufficiently long, coagulation takes place and a membrane forms. This is analogous with the formation of Curschmann's spirals in asthma. In most cases the stools contain no inflammatory material and the sigmoidoscope reveals a perfectly normal mucous membrane. Some catarrh may be present if the condition has been injudiciously treated with irritating purgatives or injections, when the membranes contain degenerated epithelial cells and leucocytes instead of being formed of almost pure mucus.

Symptoms.—In some cases the patient constantly suffers from abdominal discomfort and passes membranes. In others, definite attacks, which are sometimes brought on by depressing emotions, occur at intervals of weeks or months; the pain may be confined to the attacks, or there may be abdominal discomfort in the intervals. It is, however, not uncommon for the presence of membranes in the stools to be the only symptom.

The pain is situated most frequently in the left flank and iliac fossa and just above the pubes; at the same time the descending and iliac colon are often tender and can be felt as a contracted cord, in which scybala can sometimes be distinguished. Less frequently there is pain and tenderness in the cæcum and ascending colon, which are felt to be more firmly contracted than usual; the condition may then closely simulate appendicitis, but no relief follows appendicectomy. The passage of *faeces* and membranes or of the latter alone, whether spontaneously or as the result of treatment, generally gives temporary relief.

The constipation present in the intervals becomes much more severe during an attack. The stools consist of hard, small scybala, which may occasionally be moulded into thin or flat pieces as a result of anal spasm.

The mucus is secreted as very thin membranous shreds, which may form tubular casts of the colon with a diameter of anything up to an inch and a half. They are often called skins by the patient, and have been mistaken for tapeworms; they are sometimes rolled into a ball, which can only be disentangled by washing in water. The mucus may be transparent like ordinary mucus or opaque like fibrin; its colour is grey-white, but it is often stained by *faeces* and rarely by blood. The membranes may be passed alone or with scybala.

Functional nervous symptoms of many kinds are generally present, and the patient always tends to become depressed and hypochondriacal.

Intestinal Sand.—The passage of intestinal sand is generally associated with muco-membranous colic. Small quantities of sand, which would otherwise escape detection, can often be discovered by running water on the the *faeces* until the greater part is washed away. True intestinal sand must be distinguished from the false sand formed of wood-cells, which is sometimes passed by individuals who have eaten a large quantity of pears and more rarely of bananas. True intestinal sand is composed of pale yellow or reddish-brown granules, very irregular in shape and never crystalline.

Their most characteristic constituents are the insoluble calcium soaps of palmitic and stearic acids; an approximately equal quantity of calcium phosphate is also present.

Prognosis.—Muco-membranous colic is a very chronic condition. If treatment is begun at an early stage recovery generally follows, but when it has been present for many years the outlook is unfavourable, and even if improvement occurs, the likelihood of a relapse is considerable.

Treatment.—A patient suffering from muco-membranous colic should be treated with the object of removing the two underlying factors—the abnormal condition of the nervous system and the constipation. The former calls for rational psychotherapy. The patient should be discouraged from making minute investigations of his stools; he should be told to be satisfied if he feels better without looking to see how much mucus is passed. He may feel perfectly well in spite of the presence of mucus; but he will often only remain so for as long as he is unaware that he is passing it.

The constipation requires treatment by diet, massage, drugs, and enemata. The best results are generally obtained with a generous mixed diet containing a plentiful supply of those articles which have already been described as useful in uncomplicated constipation on account of their chemically stimulating properties, but excluding raw vegetables in salads and pickles, fibrous vegetables such as celery, and the skins and pips of fruit. Mustard, pepper and spices of all kinds should be prohibited. Smoking should be restricted, and in severe cases should be entirely prohibited.

At the commencement of treatment any accumulation of *fæces* in the colon must be removed. This can best be done by an enema of 6 ounces of paraffin given in the evening and retained during the night. Once the colon is empty, the reaccumulation of *fæces* can often be prevented by the administration of liquid paraffin and agar-agar or coreine in order to soften the stools. If this does not result in the passage of a satisfactory stool each day, the further treatment depends upon whether the stasis is in the proximal part of the colon, in which case a mild aperient, such as infusion of senna pods, is required, or in the pelvic colon, when treatment by paraffin enemata without aperients is indicated.

As in the case of uncomplicated colon spasm belladonna is the most useful drug for combating the pain; small doses of bromide may also be given to diminish the irritable condition of the nervous system. When the pain is severe it may be necessary to add codeine.

Local treatment of the mucous membrane of the colon by so-called Plombières douches should only be used in the exceptional cases in which other treatment has failed to give relief. As the patients are always self-centred, it is of the utmost importance to avoid encouraging them to concentrate upon their bowels and their excreta by irrigating the colon unless this is absolutely necessary. Intestinal lavage can be given at home; but it is generally more effective at one of the spas such as Harrogate, Llandrindod Wells, Bath, Buxton or Châtel Guyon, at which there are special facilities for carrying it out. Normal saline solution should be used if the treatment is given at home, and injections of soap and water, antiseptics and astringents should be avoided, as they tend to aggravate the condition by irritating the mucous membrane. At the various spas the natural waters are generally used for the purpose.

INTESTINAL CARBOHYDRATE DYSPEPSIA

Under normal conditions the starch taken in food is digested by the ptyalin of the saliva, the amylopsin of the pancreatic juice and the diastase of the juice secreted by the small and large intestines. The ptyalin is least important, as it is rapidly destroyed by the first trace of free hydrochloric acid with which it comes into contact in the stomach. The amylopsin is also comparatively unimportant, as the digestion of starch is generally unimpaired in advanced pancreatic disease, though much undigested fat and meat appear in the stools. The diastase secreted by the small intestine is, however, essential for the efficient digestion of starch, and when for any reason its secretion is deficient, a more or less considerable quantity of unaltered starch reaches the colon. It was formerly believed that the starch in vegetable food could be digested only when the cellulose had been broken up by cooking, or, if eaten raw, after it has been dissolved by the action of a hypothetical cellulose-splitting ferment in the small intestine or of bacteria in the colon. It has, however, recently been shown that the cellulose walls of vegetable cells are not broken by cooking, and a cellulose-splitting ferment has never been proved to exist in the human alimentary tract. It is now known that bacteria do not normally take any part in the digestion of carbohydrates, which is almost confined to the upper part of the small intestine. Ferments can penetrate the unbroken walls of vegetable cells and digest the starch within them, the sugars produced passing out into the surrounding media, from which, owing to the absence of bacteria, they are absorbed without undergoing fermentation.

Normally starch is completely digested in the upper part of the small intestine and none reaches the cæcum. When the secretion of the small intestine is deficient, ptyalin, and especially amylopsin, can completely digest free starch or starch in cells with broken walls, but the starch in intact cells reaches the cæcum. Here the diastase of the cæcal secretion penetrates the cells, but the sugars which pass into the surrounding media are attacked by bacteria which are present in very large numbers, and they undergo fermentation before there is time for much absorption to take place. The symptoms of carbohydrate intestinal dyspepsia are caused by the carbon dioxide and acetic and butyric acids produced by this fermentation.

In most cases of carbohydrate intestinal dyspepsia there is a history of food-poisoning or of some intestinal infection. The condition, however, can develop only if the damage is confined to the small intestine and the stomach and colon are spared. Thus it is never associated with achlorhydria, as the ptyalin of the saliva can compensate for the absence of the small intestine diastase when there is no free hydrochloric acid in the stomach to destroy it. When colitis is present as well as enteritis, the undigested starch which reaches the cæcum passes through the whole colon without undergoing digestion, as the digestive secretion of the colon is as deficient as that of the small intestine and little or no diastase is present in the fæces. Consequently no sugar is set free and no fermentation occurs either in the colon or on incubation of the stools, in spite of the fact that they may contain a considerable quantity of starch.

Symptoms.—The chief symptom of intestinal carbohydrate dyspepsia

is a widespread feeling of discomfort and fullness in the lower part of the abdomen, caused by distension of the colon with carbon dioxide. During the day gas often collects in the splenic flexure, which is the highest point in the colon: the discomfort produced in this way may be mistaken by the patient for gastric flatulence, and aerophagy often results from his attempt to relieve himself by belching. During the night the gas collects in the rectum, which is then as high as any other part of the colon; consequently most gas is passed during the night and on waking in the morning. The discomfort is generally increased by meals as a result of exaggeration of the gastro-colic reflex. It is often greatest during the night, and is a very common cause of insomnia, which can be cured at once by a suitable diet. The excess of gas produces borborygmi, the noise of which may itself be enough to keep a patient awake. The irritation of the bowel caused by the gas and organic acids may cause spasm: the patient then complains of actual pain, this condition being the commonest cause of colon spasm. Excessive quantities of odourless flatus are passed, and some relief is always felt after its escape.

As a result of the enteritis which is generally present, the passage of the chyme through the small intestine is abnormally rapid. This can be demonstrated with the X-Rays, even when the irritation of the colon is insufficient to cause any diarrhoea and the X-Rays show no change in the normal rate of passage through the colon. In severe cases attacks of mild diarrhoea are common, much gas being always passed with the stools, which are acid and have an unpleasant, sour, but not putrefactive, odour when they are liquid. The diarrhoeic stools always contain an obvious excess of undigested vegetable matter, and if kept for some hours bubbles appear as a result of fermentation of the undigested carbohydrates they contain.

The stools should be examined whilst the patient is on his usual diet. Microscopical examination reveals the presence of large numbers of starch granules, which are still within their cellulose envelopes; they are stained blue with iodine. Few or none are present in normal fæces. In contrast with the stools in pancreatic achylia there is no excess of fat or of striated muscle-fibres. Knott has shown that the normal enterococci of the colon are present in considerable excess, but that the number of *B. coli* is not increased and no pathogenic organisms are found. On giving a starch-free diet the excess of enterococci rapidly disappears: it is clear, therefore, that they are not the cause of the condition, as has generally been supposed, but the result of the excess of starch and sugar which is present in the colon and forms an excellent culture medium for the multiplication of these bacteria.

If a small quantity of fæces is mixed with water and incubated for 24 hours, any gas given off being collected, the fermentation which has been taking place in the colon in intestinal carbohydrate dyspepsia continues *in vitro*, and a considerable quantity of odourless gas is evolved, the fæces at the same time becoming very acid, whereas no gas is evolved from normal stools. In putrefactive diarrhoea, which is due to insufficient digestion of meat, a smaller quantity of foul gas is evolved and the fæces become strongly alkaline.

Treatment.—The treatment of carbohydrate intestinal dyspepsia is simple. Sugars are perfectly digested, and in all but the most severe cases,

in which chronic diarrhoea is present, free starch, as in flour and bread, is well digested, as the pancreatic amylapsin can deal with it. It is only necessary to cut off all starch in intact cells from the diet. In mild cases it may be enough to prohibit potatoes. In severe cases, especially when diarrhoea is present, it is necessary to exclude all vegetables and fruit, whether cooked or raw. Within a week the excess of enterococci disappears from the stools, which no longer ferment on incubation. It may be necessary to avoid potatoes and other root vegetables for a considerable period and sometimes permanently.

If a diastatic ferment of vegetable origin is taken with each meal, less restriction in diet is required, as in contrast with the amylapsin of pancreatic preparations it is very slowly destroyed by the gastric juice.

A tablespoonful of powdered charcoal may be given in a small quantity of water morning and evening to absorb any gas which is still produced, but this is quite unnecessary if a sufficiently strict diet is ordered. It is much better to prevent the production of gas than to provide for its absorption, as the condition can be permanently cured only by curing the enteritis, which is kept active by the mechanical irritation of undigested vegetable matter and the chemical irritation of the products of bacterial activity on starch.

As the excess of enterococci present is a result and not the cause of the condition, which is due to deficiency of succus entericus and not an infection with streptococci or other organisms, vaccine treatment is quite useless. I have seen many patients rapidly cured by diet alone after having undergone many months of treatment by inoculation without the slightest benefit. Colonic lavage, which is almost as popular a treatment, is, of course, equally futile.

ORGANIC DISEASES OF THE COLON

COLITIS

• Inflammation of the colon may be general or localised to one segment. Thus inflammation of the cæcum (typhilitis), cæcum and ascending colon, pelvic colon, rectum (proctitis), or pelvic colon and rectum (pelvi-rectal colitis) may occur alone, but except in the case of the two last, localisation is rarely absolute.

Although enteritis frequently causes secondary colitis, the reverse is very rare, as infective and irritating material from the ileum must pass along the colon before it is evacuated, whereas the ileo-cæcal sphincter prevents the spread of infection from the cæcum to the ileum.

The inflammation is generally limited to the mucous membrane, but it occasionally involves the deeper tissues and may spread to the peritoneum (pericolitis). The inflammation may be catarrhal or ulcerative, and chronic or acute.

The term *mucous colitis* should be abandoned, as mucus is passed in all forms of colitis; moreover, most cases so diagnosed are not suffering from colitis at all, the excess of mucus being the response of the mucous membrane of the normal intestines to irritation by purgatives or of that of the pelvic colon and rectum to irritation by scybala. The term *muco-membranous colitis*

should also be replaced by muco-membranous colic, as it is a functional condition and not a form of colitis at all (p. 627).

ACUTE CATARRHAL COLITIS

Ætiology.—Acute catarrhal colitis occurs most frequently as a result of food poisoning, either alone or associated with acute gastritis and enteritis. It may also be a symptom of specific fevers and various toxæmias, especially uræmia.

Symptoms.—The chief symptom is diarrhœa, the stools being frequent, fluid and offensive; they contain mucus, sometimes traces of blood, but no excess of food residue, unless the small intestine is simultaneously affected. Abdominal discomfort is present, and paroxysms of colicky pain are frequent. In severe cases there may be well-marked general symptoms with a high temperature and a rapid pulse. As a rule the condition rapidly improves, but it may develop into chronic colitis.

Treatment.—The treatment is the same as that for Acute Diarrhœa (p. 616).

CHRONIC CATARRHAL COLITIS

Ætiology.—The most common cause of chronic catarrhal colitis is the habitual use of purgatives, which are frequently taken even in the absence of constipation. Infection of the bowels with pathogenic organisms, introduced in the food or water or coming from some septic focus in the mouth, pharynx or appendix may cause a chronic infective, catarrhal colitis, which may also be the sequel of an attack of acute colitis or the colitis of some specific infection, such as amœbic or bacillary dysentery.

Symptoms.—Diffuse discomfort and a sensation of fullness are commonly present in the lower part of the abdomen. Slight attacks of colic may occur, but in many cases there is no actual pain. The abdomen is often somewhat distended and tender. The discomfort is generally worse after meals and is relieved if the bowels are well opened. In infective cases and those following an attack of acute colitis, diarrhœa is generally present, mucus and occasionally traces of blood being found in the fluid stools, but there is no excess of food residue unless enteritis is also present.

The presence of mucus in the stools is often regarded as sufficient evidence to prove that colitis is present. But it is a function of the healthy mucous membrane to secrete mucus to protect itself against mechanical and chemical irritants. Consequently the unformed, clear mucus passed with hard fæces in constipation, and especially in dyschezia, does not indicate that colitis or proctitis is present, and the same is true of the mucus passed with fluid stools, when irritating aperients have been taken. Only if mucus is passed with soft stools when no purgative has been given can it be regarded as of any diagnostic importance. On the other hand, pus and red blood corpuscles both indicate the presence of some organic condition, though the possibility of hæmorrhoids as the source of the latter, must, of course, be remembered.

Treatment.—The teeth should be put into good order and any other source of infection should be removed. The food must be thoroughly masticated and should be of an unirritating character. The use of purgatives should be avoided as much as possible, though liquid paraffin is often useful, as it

makes the stools soft. In infective colitis a liquid culture of *B. acidophilus* should be taken, and an autogenous vaccine may prove of value if definitely pathogenic organisms have been isolated from the stools. Belladonna should be given before meals with the addition, if diarrhoea persists, of codeine.

ULCERATIVE COLITIS

Ætiology.—Ulcerative colitis is a condition which occurs sporadically in England and other countries in which dysentery is not epidemic. Young adults are most frequently affected, and the disease is equally common in men and women. It is infective in origin, and from the very close similarity it bears to bacillary dysentery it seems probable that it must be due to some aberrant form of *B. dysenteriae*. In four of my cases and eight others of which I have knowledge, Flexner's dysentery bacillus was isolated from the stools, swabs from ulcers, or a scraping of the floor of an ulcer obtained with a sharp spoon, and it has often been found in institutional epidemics and in the epidemic colitis of infants, conditions which are clinically and pathologically very similar. In a small number of my cases one of the parenteric organisms, such as *B. asiaticus* and *B. watereka*, has been isolated from the stools, and the patient's blood has agglutinated it. The enterococcus believed by Bergen to be the cause of ulcerative colitis has been found in England as frequently in normal stools as in stools from cases of ulcerative colitis and does not appear to be pathogenic.

Ulceration of the colon also occurs in rare cases of uræmia, probably as a result of the excretion into the large intestines of toxins, which cannot be excreted by the diseased kidneys, and in mercurial poisoning.

Pathology.—The primary change is an acute inflammation of the mucous membrane of the colon. Minute submucous hæmorrhages and patches of localised necrosis then occur, and the gradual separation of the necrotic tissue leads to superficial ulceration. The floor of the ulcers is formed by the submucous or muscular coat, the ulcers tending to spread superficially rather than deeply.

Symptoms.—The onset is sometimes acute with severe diarrhoea and fever. More commonly it is subacute and insidious, the first symptom noticed being the passage of blood and mucus with or without diarrhoea. Even in cases which appear to begin acutely a history can often be obtained of slight intestinal irregularity, with the occasional passage of mucus or blood, for many months or even several years before the onset of severe symptoms.

Diarrhoea is always present; as many as twenty stools, most of which are quite small, may be passed in the day. Blood, pus and mucus are passed with fluid faeces and also alone. In quiescent periods they may appear to be absent, but microscopical examination of the stools shows that this is not the case. Blood may be passed in large quantities by itself, but it is generally mixed more or less intimately with the mucus and pus. It is bright red, and never produces black tarry stools, such as are seen with gastric and duodenal ulcer. It is mostly fluid, but small clots are often present. The mucus is clear or opaque owing to the presence of pus; membranes are never passed. In most cases small collections of pus are easily recognised with the naked eye in addition to that mixed with the mucus and fluid faeces.

Abdominal discomfort is often, but not always, present. Actual pain

is rare except immediately before defæcation, when colic may occur; this disappears as soon as the bowels are opened, especially if flatus is passed. Tenesmus is unusual and only occurs if the anal canal is involved. The abdomen is sometimes slightly distended, but in many cases it is retracted. Tenderness is often completely absent, even in severe cases, but pressure over the colon, especially in the left iliac fossa, may cause discomfort. If the tenderness is considerable, the inflammation has generally spread to the peritoneum and local peritonitis is present. A moderate degree of muscular rigidity is often present in severe cases, especially when there is any local peritonitis.

In rare cases non-suppurative multiple arthritis develops; this is strictly analogous to the arthritis which may follow bacillary dysentery.

Diagnosis.—The association of blood in the stools with pus and mucus indicates the presence of ulcerative colitis or a growth of the pelvic colon or rectum. A growth can be excluded by rectal and abdominal palpation, and by the sigmoidoscope. Even if the growth is too high to be reached by the instrument, its presence is rendered very probable when the accessible part of the colon appears normal, and blood, mucus and pus are seen coming from the inaccessible part.

If the patient has been in the East the possibility of dysentery should be considered, though the absence of such a history does not exclude it, as I have seen several cases of amœbic dysentery in people who have never been out of England. Mucus obtained direct from the surface of an ulcer through the sigmoidoscope should, therefore, always be examined for amœbæ and cysts as well as bacteriologically, and the agglutinating power of the patient's serum should be tested against various strains of *B. dysentericæ*. The sigmoidoscopic appearance of the mucous membrane in bacillary dysentery and ulcerative colitis is identical, but in the latter condition the serum rarely agglutinates *B. dysentericæ*. Amœbic dysentery is, however, so distinct that a definite diagnosis can easily be made from the sigmoidoscopic appearance alone. Small, round, red elevations are seen on the otherwise normal-looking mucous membrane, corresponding with the collection of broken-down material in the submucous tissue caused by the invasion of *Entamœba histolytica*. In the centre of each elevation is a depressed yellowish ulcer, where the submucous abscess has broken through the mucous membrane. I have seen one case of thrombocytopenic purpura with only a few cutaneous petechiæ, in which the passage of blood in the stools had led to a diagnosis of ulcerative colitis, but the sigmoidoscope revealed innumerable minute submucous hæmorrhages without any actual inflammation. A similar hæmorrhagic proctitis occurred in another case after avertin anæsthesia.

Digital examination of the rectum is only painful when the anal canal is inflamed. The thickened mucous membrane and the ulcers are readily felt with the finger when the rectum is involved.

An examination should always be made with a long proctoscope; in the rare cases in which the rectum is healthy a sigmoidoscope must be used. An anæsthetic is never required, and if the instrument is carefully introduced under visual guidance without inflation and only as far as it goes without difficulty, there is no danger. The mucous membrane is bright red, thick, and sometimes granular. It bleeds very readily when touched, and small

submucous hæmorrhages are frequently seen. Its surface is covered with blood-stained, purulent mucus, some of which should be removed on a sterile swab for bacteriological and cytological examination. Superficial ulcers are invariably present; but in early cases they may be so small that they are difficult to recognise without a magnifying eye-piece. Later they are large, and are sometimes so extensive that only small islets of mucous membrane are left, which may feel like small, flat polypi on rectal examination, the floor of the confluent ulcers being mistaken for the surface of the mucous membrane. The ulcers are always superficial with irregular edges; the thick mucous membrane is not undermined. The floor of the ulcers appears greyish-yellow when the blood and mucus are wiped from their surface.

In acute cases, and in acute exacerbations of more chronic cases, irregular fever is generally present. Apart from this, the patient has generally a good appetite. The constant diarrhœa leads to progressive emaciation and weakness; but in mild cases the patient may feel so well that he is unwilling to undergo treatment in bed. The loss of blood leads to secondary anæmia, which may be severe; the amount of hæmoglobin is often only 50 per cent. of normal, and may fall to 20 per cent. In such cases œdema of the ankles and ascites may develop.

Complications.—In the course of healing, strictures, which may be multiple and are generally of considerable length, may develop, especially in cases of long standing. A narrowing can sometimes be recognised with the sigmoidoscope, but the exact degree and localisation can only be discovered with the aid of the X-Rays. It is very difficult to distinguish between an organic stricture and spasm with the sigmoidoscope and with the X-Rays, and repeated observations are therefore essential before deciding upon operative treatment. It is much safer to examine the colon after a series of opaque meals given within a few hours rather than an opaque enema, which may carry infective material from the distal colon to the still healthy proximal colon. Moreover, a stricture only requires surgery if it causes stasis, which can be recognised with an opaque meal, but not with an enema. The X-Rays also give some idea of the extent of colon involved, as the normal "haustration" disappears when severe inflammation is present; in the majority of early cases the distal half of the colon or the pelvic colon and rectum are alone affected. The symptoms generally do not alter with the development of the strictures, as the stools are so fluid that they pass without difficulty through the narrowed bowel.

In other cases healing is associated with the development of multiple minute polypi: this is one cause of polyposis of the colon. This condition may give rise to no symptoms, but the polypi are liable to become malignant. In my experience the application of deep X-Rays may result in their complete disappearance.

General peritonitis is a very rare complication, and is not due to perforation, but to direct spread of infection through the wall of the colon. Localised abscesses are still more unusual except in the perianal region, multiple fistulæ-in-ano being not uncommon; if undiscovered they may give rise to recurrence after apparent recovery.

Prognosis.—Very acute ulcerative colitis may cause death in a few weeks. More commonly the condition becomes chronic with periodic acute

exacerbations, and thus approximates to the ordinary form of ulcerative colitis, in which the onset is insidious and the course very prolonged. Death generally results from cachexia, owing to the prolonged diarrhoea and constant loss of blood. With adequate treatment, however, recovery is the rule.

Treatment.—If a sigmoidoscopic examination is always made when a patient passes blood or mucus in his stools, or is suffering from diarrhoea the cause of which is not obvious, ulcerative colitis can often be recognised at such an early stage that recovery will be rapid. More commonly treatment continued for many months and even for a year or more is required, but no case should be regarded as cured until a further sigmoidoscopic examination has shown that all ulceration has disappeared and the mucous membrane is no longer inflamed.

The patient should be kept warm and recumbent in bed until no blood has been passed for at least a fortnight, the bowels are not opened more than twice a day, and no ulceration and no inflammation can be seen with the sigmoidoscope. But the patient should continue under strict treatment till the mucous membrane appears to be perfectly normal, and he should be careful about his diet and keep his stools soft with liquid paraffin for several years, as the danger of recurrence remains for a prolonged period.

An abundant but light mixed diet should be given, as the small intestines are never involved. The food must be thoroughly masticated. Everything which could irritate the colon mechanically should be prohibited; vegetables are only allowed if they have been passed through a fine sieve, and only the juice of fruit should be given.

The colon should be irrigated every day with tannic acid solution. An injection of warm saline solution should be given through a soft catheter before, in order to clear away as much faeces, blood and mucus as possible; this should be retained for about 5 minutes. The tannic acid solution (gr. $\frac{1}{2}$ -ij to the ounce) is then run in very slowly at a pressure of not more than 12 inches of water through a soft catheter introduced not more than $1\frac{1}{2}$ inches beyond the anus. The fluid should be retained for gradually longer periods up to half an hour. The quantity of fluid to be used depends upon the extent of colon involved; if the X-Rays show that the whole colon is inflamed a pint and a half should be introduced, but if it is confined to the pelvic colon and rectum not more than half or three-quarters of a pint is required, and the patient should remain sitting after the injection in order to prevent the fluid running into the proximal colon. When the inflammation is confined to the rectum, daily packing through a proctoscope with strips of gauze soaked in 10 per cent. neoprotosil is often very effective.

When the patient is very ill as a result of long-continued loss of blood from the colon, transfusion is of great value and occasionally leads to rapid recovery.

In my experience vaccine treatment has generally very little effect, doubtless because of the extreme difficulty of discovering the organism which is really responsible for the colitis. If it can be identified with certainty, very small doses of an autogenous vaccine may be tried in addition to, but never as a substitute for, other treatment. A drachm of an active liquid culture of *B. acidophilus* may be given three times a day between meals. Sources of infection such as apical dental abscesses or pyorrhoea alveolaris should be thoroughly treated.

The intravenous injection of 20, 40, 60, 80, and 100 c.c. of polyvalent anti-dysenteric serum on consecutive days and then 100 c.c. for a few extra days may result in extremely rapid healing. The treatment is often so effective that the period of treatment is shortened from several months to a few weeks. In spite of the severe general reaction, which occasionally takes place and may necessitate cessation before the course is complete, serum should therefore be tried in every case. It may also be effective when given subcutaneously in daily doses of 20 c.c., but the treatment must be continued for a longer period.

The administration of half an ounce of finely powdered charcoal two or three times a day leads to the absorption of gas and a great diminution of any colic which is present, as the latter is caused by intestinal flatulence, and if the stools are offensive they become odourless.

With the medical treatment described above I have seen no cases in recent years in which appendicostomy was required. In my experience improvement after operation is not as a rule more rapid than under purely medical treatment, and the mortality is over 20 per cent., whereas in a consecutive series of 30 cases treated medically, many of extreme severity, recovery occurred in all but one. If a fistula or small abscess develops in connection with the anal canal, it is most important that it should be thoroughly treated, or secondary infection of the healing mucous membrane of the rectum and colon is certain to occur. If an organic stricture causing definite stasis is present, a short-circuiting operation should be performed; this was done successfully in two of my cases, in one of which it was necessary to excise the short-circuited portion at a later date.

TUBERCULOUS ENTERITIS AND COLITIS

Ætiology.—Miliary tubercles may be present in the intestines in general tuberculosis, but they have no clinical importance. Primary infection of the bowels from tuberculous milk is not infrequent in children, but is comparatively rare in adults. Secondary infection from swallowing tuberculous sputum is very common, ulceration being present in 50 per cent. of fatal cases of pulmonary tuberculosis, in some of which, however, it is probably due to pyogenic organisms and not to the tubercle bacillus. The lower end of the ileum, the appendix and the cæcum are the parts most frequently affected.

Symptoms.—In many cases no symptoms are present, although extensive ulceration may be found post mortem. Tuberculous enteritis should be suspected in children suffering from diarrhoea with fever, abdominal distension, enlarged glands, anæmia, wasting and weakness. It should also be suspected when pulmonary tuberculosis is associated with diarrhoea, especially if abdominal pain and tenderness are present and blood is found in the stools. Tubercle bacilli may be present as a result of swallowing infected sputum even with healthy intestines. In the absence of abdominal pain the diarrhoea in advanced phthisis is sometimes due to the achlorhydria which is commonly present.

Perforation of a tuberculous ulcer is rare owing to the adhesions which form between the coils of intestine. Cicatrisation of an ulcer may lead to

single or multiple strictures of the small intestines ; as these are incomplete, and the contents of the bowel are fluid, obstruction is rarely produced. External adhesions and the formation of bands may, however, lead to acute intestinal obstruction.

Tuberculous ulceration of the last few inches of the ileum may produce reflex dyspepsia similar to that caused by chronic appendicitis. In such cases when the terminal ileum is visualised with the X-Rays it is found to be tender ; its lumen may be irregular and thickening may be recognised on palpation. The X-Rays may show a group of opaque glands in the ileo-cæcal angle. The stools generally contain occult blood, and there is often mild intermittent pyrexia. At a later stage small intestine peristalsis may become visible, and palpable stiffening of a coil of ileum, which disappears with a gurgle, sometimes occurs, although the bowels may remain regular until acute obstruction supervenes. In a case under my care multiple strictures of the colon were recognised with the X-Rays : recovery followed partial colectomy, and the strictures were found to be caused by cicatrisation of tuberculous ulcers.

Hyperplastic Tuberculosis of the Cæcum is a very rare condition, in which the ileo-cæcal sphincter and a small part of the ileum may also be involved. Chronic intestinal obstruction and the presence of a hard, mobile, non-tender tumour give rise to suspicions of cancer, which can only be dispelled after exploration. It is rarely associated with tuberculous foci elsewhere and does not ulcerate ; there is therefore no pyrexia and tubercle bacilli do not appear in the stools.

Treatment.—The treatment is that of tuberculosis in general, combined with the dietetic restrictions required for non-tuberculous colitis. Hyperplastic tuberculosis of the cæcum should be excised as soon as it is recognised.

POLYPI OF THE COLON: POLYPOSIS

Ætiology and Pathology.—Solitary polypi of the colon are common, and cases with two to twelve are not infrequent. True polyposis, in which the whole or part of the colon is studded with innumerable polypoid adenomata, is very rare.

The polypi generally begin as small flat patches of mucosal overgrowth which soon become polypoid. Less frequently exactly similar polypi develop in the process of recovery from ulcerative colitis ; they are generally present in small numbers, but occasionally a condition of generalised polyposis develops which is indistinguishable from the primary condition.

Most cases of primary polyposis are familial, several members of one or more generations of a family being affected. Less frequently single polypi are also familial.

Males are more often affected than females, and the symptoms generally begin before the age of 30.

Symptoms.—Loss of bright red blood from the bowel is generally the first and it may be the only symptom. Recurrent rectal hæmorrhage in a child is most commonly caused by a polyp. In polyposis diarrhœa always develops sooner or later, and the fluid fæces are mixed with mucus, pus and bright blood, being indistinguishable from those passed in ulcerative colitis. The

hæmorrhage may lead to severe anæmia, and the diarrhœa to malnutrition and, when it begins in childhood, to infantilism. Tenesmus and abdominal pain are uncommon.

The polypi can often be felt on rectal examination. They are easily recognisable by procto-sigmoidoscopy, and their exact extent can be estimated by means of an opaque enema which gives a characteristic picture, showing rounded semi-translucent areas in the shadow of the colon.

Polypi are the most common exciting cause of chronic intussusception.

Both single and multiple polypi show a considerable tendency to become malignant, and the majority of patients with familial polyposis ultimately die of carcinoma. In most cases of carcinoma of the rectum and colon the lesion is probably grafted on a simple polypous adenoma. Thus Dukes found adenomata in 75 per cent. of 33 specimens of carcinoma of the rectum and pelvic colon, and in nearly all very early cases of carcinoma the adenomatous origin can be recognised. Malignant degeneration may occur in more than one polyp either at the same time or after an interval.

Treatment.—Single polypi should be removed when possible through a speculum. Multiple polypi in the rectum and pelvic colon can be destroyed by diathermy cautery. I have seen them disappear under treatment with deep X-Rays, and radium is also sometimes successful. When the whole colon is involved with polyposis, colectomy is the only rational treatment, and those polypi present in the remaining part of the pelvic colon and the rectum can be destroyed by diathermy, deep X-Rays and radium.

CANCER OF THE COLON

Ætiology.—Primary columnar-celled carcinoma of the colon attacks men and women with equal frequency. It is most common between the ages of 40 and 65, although cases have been recorded in early childhood.

Pathology.—Only 3 per cent. of cases of intestinal cancer affect the small intestine. Of the remainder 60 per cent. are in the rectum and at the pelvi-rectal flexure, and 20 per cent. in the iliac and pelvic colon: thus 80 per cent. of cases occur in parts of the colon where the faces are solid. Nearly half of the remainder are in the cæcum.

The adenomatous origin of colonic carcinoma is discussed in the previous section.

Extension to the peritoneum and secondary deposits in the lymphatic glands, liver and other organs develop later and rather less frequently with cancer of the intestine than with cancer in most other situations, obstruction occurring in more than 50 per cent. of cases before the glands are involved. The prospect of a radical cure by operation, if an early diagnosis is made, is therefore comparatively good. The rectum has a moderate supply of lymphatics and gives operative results intermediate between gastric and intestinal carcinoma.

Symptoms.—The possibility of cancer of the intestine should be considered whenever an individual over the age of 35, whose bowels have previously been regular, develops, without change of diet or habits, constipation or diarrhœa, or when a patient of the same age, who is habitually constipated, becomes more so without obvious reason. Constipation occurs

earliest in the common annular form of intestinal cancer, which narrows the circumference of the bowel while the actual size of the growth is still very small. Less obstruction is caused by papillomatous carcinoma, which forms a friable and ulcerated mass, projecting into, but not obliterating, the intestinal lumen; constipation is at first intermittent and relieved by purgatives, which gradually become less effective and cause more pain. Enemata are generally of use for a longer period, but they also finally fail to act. Sometimes, however, there is persistent diarrhoea from the start, especially when the growth is situated in the pelvic colon. More frequently the initial constipation is interrupted by attacks of diarrhoea. In the majority of cases the constipation becomes steadily more severe until it ends in complete obstruction, which is sometimes hastened by the impaction of a hard mass of faeces in the narrowed lumen.

The stools do not generally differ in shape from those seen in ordinary constipation. Occasionally thin pieces, resembling the faeces formed in some cases of spastic constipation, are passed, especially when the growth is in the pelvic colon or in the rectum; they sometimes owe their shape to spasm of the anal sphincter, produced reflexly by the growth or by the irritating discharge from its surface, but I have also seen ribbon-shaped faeces appear through a stricture six inches from the anus during a sigmoidoscopic examination. The stools in cancer of the rectum and lower part of the pelvic colon generally contain obvious blood, pus and mucus, often without any faecal matter. They may closely resemble those of simple ulcerative colitis, but fragments of more or less solid faeces can often be recognised, whereas in ulcerative colitis the faeces are always unformed. When the growth is proximal to the middle of the pelvic colon, blood can rarely be recognised with the naked eye, but occult blood can always be found by the guaiac test; the spectroscope often shows that acid hæmatin as well as hæmatoporphyrin is present in contrast with the occult blood of gastric and duodenal origin, which gives the former spectrum alone unless the quantity present is unusually great.

Vague discomfort in the lower part of the abdomen is often present, sometimes without any irregularity of the bowels, and slight attacks of colic occur when constipation becomes severe, but they rarely reach any great intensity until the obstruction is almost complete. In some cases, especially in cancer of the cæcum, hepatic flexure and splenic flexure, the pain always travels in a definite direction to a certain point, where the patient occasionally feels a rumbling sensation; this generally corresponds with the situation of the growth. When the pelvic colon is involved, the pain is always below the umbilicus and is often most marked on the left side.

The over-activity of the colon above the obstruction leads to hypertrophy of its musculature. When the obstruction becomes complete, failure of the muscle ultimately occurs and extreme paralytic distension results; ulceration and perforation, especially of the cæcum, may follow.

When the obstruction is sufficient to give rise to severe colic, strong spasmodic contractions or "stiffening" of the intestine are often visible and palpable. They never occur in the colic associated with lead poisoning or colitis, and only very rarely with obstruction due to simple impaction of faeces.

Symptoms of cancerous cachexia are generally absent in the early stage; they are most marked when the growth is extensive or much

ulcerated, and when frequent small hæmorrhages have occurred. Progressive loss of weight and strength and increasing anæmia are the chief general symptoms; the appetite is often diminished, but the occasional association of a good appetite with progressive emaciation is, in the absence of pyrexia, very suggestive of a growth. The nutrition suffers most and anæmia is most marked when the tumour is proximal to the hepatic flexure, whereas obstructive symptoms are generally more severe when the distal part of the colon is involved.

In about 30 per cent. of cases when the patient is first seen, a tumour is palpable either on abdominal or rectal examination. In some of the remainder the growth is inaccessible to palpation owing to its situation at the splenic flexure; in others the tumour is too small to be palpable. It is often impossible to reach a growth in the lower end of the pelvic colon or at the top of the rectum either by abdominal or rectal examination. In such cases the sigmoidoscope alone makes an early diagnosis possible. If acute obstruction is not an early occurrence, the growth develops into a large and easily palpable tumour, which invades the neighbouring peritoneum and viscera. The tumour often varies in size from time to time, as it is formed not only by the growth itself, but partly by impacted feces or by thickened peritoneum and adherent coils of intestine, with perhaps a localised abscess. The disappearance of a tumour after treatment with purgatives or enemata does not therefore mean that cancer is absent, even if its disappearance is associated with improvement in the symptoms. For a mass of feces can become impacted above a cancerous stricture and produce obstruction, which may be partially relieved when the feces are removed. A diagnosis of cancer can only be excluded when the disappearance of the tumour is accompanied by complete and lasting cure of all the symptoms. The tumour produced by a growth is hard; it is rarely very tender, unless complicated by local peritonitis. When situated in the ascending, descending or iliac colon it is generally fixed; in the cæcum and transverse colon it is frequently very movable.

The X-Rays often afford considerable help in diagnosis. The shadow of the colon may be visible as far as the seat of obstruction unusually soon after the opaque meal; little or no barium may pass beyond this point for a considerable time, but this may also occur in simple constipation. The passage of an opaque enema is often obstructed at a period in the disease when an opaque meal is not delayed. In most cases, especially when an enema is used, a filling defect caused by the tumour can be observed. When a tumour is present, the combination of abdominal palpation and X-Ray examination shows whether any delay in the passage of feces occurs in the neighbourhood of the tumour and whether the latter arises from some part of the alimentary canal. It is important to note, however, that the X-Rays may completely fail to give any evidence of a growth until some months have elapsed since the onset of symptoms, but with the improvement in technique during the last few years this should now happen very rarely.

In exceptional cases symptoms are produced by complications before the intestinal functions become affected. Thus secondary deposits in the brain may cause cerebral symptoms sufficient to overshadow everything else, and an abscess developing in connection with an ulcerated growth or a stercoral ulcer above the obstruction, or general peritonitis resulting from perforation of the ulcer may constitute the earliest clinical manifestation. I have seen two

cases in which no symptoms occurred until the development of a gastro-colic fistula.

Diagnosis.—The diagnosis depends upon the history combined with the results of abdominal and rectal palpation, examination of the stools for visible or occult blood, sigmoidoscopy and the X-Rays. A tumour in the right iliac fossa may be caused by an inflammatory mass developing round a small chronic appendicular abscess and by hypertrophic tuberculous disease of the intestine as well as by cancer. In the left iliac fossa confusion with an inflammatory mass in connection with diverticula of the colon is not infrequent, but a barium enema almost invariably reveals the presence of the latter. The chronic obstruction caused by a local band of adhesions may simulate that caused by a growth, the difficulty being increased by the fact that the stools may contain occult blood.

Prognosis.—Improved methods of examination have made it possible to diagnose the large majority of cases of cancer of the colon as soon as symptoms appear and before any serious degree of obstruction has developed. As glandular involvement and secondary deposits in the liver and other organs occur comparatively late, in most such cases the growth can be completely removed, and many of my patients are still in perfect health several years after the operation. If operation be delayed until acute obstruction is present, the immediate prognosis is very bad, but in subacute obstruction a two-stage operation preceded by preparation of the patient by lavage of the colon with administration of large doses of belladonna is often successful.

Treatment.—Cancer of any part of the large intestine proximal to the middle of the transverse colon is best treated by the removal of all the colon up to three inches beyond the growth, an ileo-colostomy being simultaneously performed. Beyond this point resection of the growth and of a sufficient margin on each side with end-to-end anastomosis is more satisfactory. If the slightest obstruction is present, the operation should be performed in two stages, excision being only performed after the patient recovers from a preliminary colostomy or short-circuiting operation.

DIVERTICULOSIS : DIVERTICULITIS

Ætiology and Pathology.—Diverticula of the colon generally occur in individuals who have for many years taken aperients for constipation. Diverticula are uncommon above the middle of the descending colon and they increase in number and size as the lower end of the pelvic colon is approached, but they are very rare in the rectum owing to the thickness of its muscular coat.

Diverticula generally develop after the age of 40 and occur with equal frequency in men and women. Owing to the atrophy of the muscular coat of the colon, which occurs in old age, pressure from within produces diverticula more readily than in earlier life. The presence of fat diminishes the resistance of the intestinal wall to pressure from within, so that diverticula are especially likely to occur in the obese and often form in the appendices epiploicæ.

A large number of diverticula are generally present; some are so small that they are barely visible to the naked eye, whilst others attain a diameter of half an inch. They very rarely become larger, as secondary pathological

changes interrupt their growth. In the walls of the smaller diverticula all the coats of the bowel are represented. As they grow larger the muscular layer gradually disappears and the mucous membrane frequently becomes atrophied.

Symptoms.—*Diverticulosis*, the simple presence of diverticula of the colon, is a very common condition and gives rise to no symptoms. Their inflammation, *diverticulitis*, which occurs in about 15 per cent. of cases, especially when associated with inflammation of the surrounding peritoneum, gives rise to a variety of symptoms. Most frequently the patient complains of discomfort in the lower part of the abdomen and, after a time, attacks of colic, which gradually increase in severity and in frequency. The discomfort is generally most marked in the left iliac fossa. At the same time the constipation, for which the patient has generally taken aperients for many years, may become more severe. Aperients aggravate the pain, which is relieved to some extent by the passage of flatus or fæces. Mucus may be present in the stools, and pus cells can occasionally be discovered on microscopical examination, but obvious and occult blood is generally absent.

The temperature is sometimes slightly raised, and in acute exacerbations it may be very high and accompanied by severe constitutional symptoms with polymorphonuclear leucocytosis.

The bladder is often irritable, the patient having to pass urine with abnormal frequency. At a later stage adhesions with the bladder may develop and lead to cystitis, and in very rare cases gas and fæces are finally passed *per urethram* owing to the development of a vesico-colic fistula, diverticulitis and not cancer of the colon being the cause of the majority of cases of this condition.

Diverticulitis, like appendicitis, may cause reflex gastric dyspepsia.

Tenderness is most marked in the left iliac fossa and occasionally immediately above the pubes. The rigidity of the abdominal wall over the tender area may make it difficult to palpate the colon, but in most cases it is possible to feel the irregularly thickened and extremely tender iliac colon. Digital examination of the rectum generally reveals nothing abnormal, but I have felt a mass suggestive of a secondary malignant deposit in Douglas's pouch which was caused by thickening round inflamed diverticula of the pelvic colon. The sigmoidoscope often cannot be passed farther than the pelvic-rectal flexure or an inch or two beyond, the bowel at this point appearing to be abnormally fixed and its lumen narrowed. I have never been able to see the mouths of diverticula at the lower end of the affected portion of the pelvic colon.

An opaque meal shows that there is generally little or no delay in the passage through the bowel till the iliac colon is reached. The presence of diverticula can often be recognised when the opaque meal reaches the affected part, as some of it enters and remains in them after the rest has been evacuated. In all cases a barium enema should also be given, as whenever diverticula are present their number and localisation can be more accurately determined in this way than by any other method. They may be discovered directly the enema is given, but more often only after it has been evacuated, a double row of small rounded shadows representing the diverticula being then seen, especially in the position of the iliac and pelvic colon. They often remain visible for several days.

Diagnosis.—Discomfort and colicky pain in the lower part of the abdomen in middle-aged and elderly patients, especially if associated with increasing constipation, should raise the suspicion of diverticulitis as well as of a growth of the colon. If the pain is most marked in the left iliac fossa and if it is associated with bladder irritability, the former is the more probable diagnosis. A tender tumour in the left iliac fossa, associated with muscular rigidity, is much more frequently due to diverticulitis than to cancer. An X-Ray examination after an opaque meal and an opaque enema generally settle the diagnosis. Diverticulitis cannot be regarded as a pre-cancerous condition, as the occasional association with cancer is no more frequent than can be explained by coincidence, and the incidence of cancer in simple diverticulosis is as great as in diverticulitis. When cancer is present the stools contain pus and blood, and an opaque enema reveals a filling defect in addition to the diverticula, which do not necessarily involve the same part of the colon.

Treatment.—The accidental discovery of diverticulosis in the course of a routine X-Ray examination indicates the necessity for keeping the stools permanently soft by means of paraffin and the avoidance of pips and skins of fruit and of pickles and salads, and cooked green vegetables except as purées. No aperients should be used, as they tend to force the fluid fæces into the diverticula. In very mild diverticulitis the same treatment is effective. In more severe cases with pyrexia and abdominal rigidity the patient should be kept in bed till all signs of active inflammation have disappeared. The diet already mentioned should be given together with an ounce of paraffin three times a day. Belladonna in maximal doses may be required to control the secondary spasm. Six ounces of paraffin should be injected into the rectum every evening and retained during the night. If the bowels do not act satisfactorily in the morning, water should be run into the rectum very slowly and under very low pressure in quantity insufficient to cause pain. By this means the accumulation of fæces generally present is gradually evacuated, and the pain and inflammation subside. Contrary to what was formerly thought, very few cases require operation. Large inflammatory masses associated with a high temperature and leucocytosis may completely disappear, and a considerable degree of obstruction may be overcome. I have not seen a single case requiring operation in the last six years. Only if the symptoms become worse in spite of treatment, or if the condition is complicated by the development of an abscess, signs of spreading peritonitis, or increasing cystitis suggesting that a vesico-colic fistula is about to form is an operation indicated. It is sometimes possible to excise or short-circuit the whole of the affected portion of the bowel, but more often a colostomy has to be performed.

CHRONIC INTUSSUSCEPTION

Ætiology.—Chronic intussusception is a rare disease occurring only in adults. Twenty per cent. are secondary to innocent tumours, most of which project as polypi into the lumen of the bowel. Fifteen per cent. are secondary to malignant tumours, and 6 per cent. to dysenteric, tuberculous, and other ulcers. A case of mine was associated with chronic uræmia in a man suffering from nephritis due to lead poisoning.

For Acute Intussusception *vide* Acute Intestinal Obstruction, p. 649.

Symptoms.—A chronic intussusception may last for a month, a year or longer before it terminates in an attack of acute obstruction or of general peritonitis from perforation. It may finally reach the anus, from which it may project for some inches without preventing the passage of fæces. The onset is generally insidious; occasionally it is acute, but the severity of the symptoms generally diminishes and the subsequent progress of the case is chronic. Only about half of the cases are accompanied by constipation, diarrhoea being present in the majority of the others. The most prominent symptom is colic, occurring in attacks which steadily increase in frequency and severity, and which may be brought on by taking food or by aperients; constipation is present during the attack, and blood and mucus may be passed at frequent intervals in entero-colic and colic, but not in enteric, intussusceptions. A palpable tumour is present in half the cases; it becomes harder and longer during an attack of colic, and appears to recede in the intervals. Severe attacks are accompanied by vomiting, especially in the enteric form. Visible peristalsis and dilatation may occur in the intestines above the intussusception. An opaque enema, given for suspected chronic obstruction, may reveal the presence of an intussusception by the typical appearance it produces.

Treatment.—The treatment is always surgical.

ACHALASIA OF THE ANAL SPHINCTER (HIRSCHSPRUNG'S DISEASE IN CHILDREN AND MEGACOLON IN ADULTS)

Ætiology and Pathology.—Hirschsprung's disease is a rare condition, occurring in young children, in which the colon becomes greatly dilated and hypertrophied although no organic obstruction is present.

Megacolon is a similar condition occurring in adults; it is either the sequel of Hirschsprung's disease which has remained latent, or it may develop only in later life.

Hirschsprung's disease occurs about eight times more frequently in males than in females, but in the megacolon of adults there is only a slight preponderance of males.

In children the lower limit of the dilatation appears to be situated with equal frequency at the junction of the pelvic colon with the rectum and at the anal sphincter, but in adults it is always at the latter. From these points upwards there is a rapid enlargement, the maximum diameter being generally 3 or 4 inches higher. In most cases, especially in adults, the enlargement is confined to the pelvic colon or rectum and pelvic colon, which may be so lengthened as well as dilated that it reaches the left dome of the diaphragm or even finds its way above the liver under the right dome. In other cases, varying lengths of intestine are dilated, but the dilatation is always greatest in the pelvic colon and diminishes as it is traced towards the cæcum, the small intestine being always spared. The muscular coat of the dilated intestine is greatly hypertrophied. The hypertrophy must be a result of the increased work which the intestine has to do in order to overcome some obstruction, and peristalsis occurring in the hypertrophied colon could not fail to evacuate it, if there were no obstruction to the passage of its contents. The obstruction

is primarily due to absence of the relaxation of the circular muscle fibres of the anal sphincter, which should occur during defæcation ; it is analogous to achalasia of the cardia, which causes dilatation and hypertrophy of the œsophagus. It probably depends, like the latter, upon organic changes in Auerbach's plexus in the region of the sphincter ; these are doubtless secondary to inflammation of the mucous membrane, which disappears completely but leaves behind permanent degeneration of the nerve tissue. Such degenerative changes have been observed in a case of Hirschsprung's disease by Munro Cameron. In some cases, especially in children, a kink is produced by the greatly dilated pelvic colon overhanging the rectum, which on account of its thicker walls and its fixed position in the pelvis cannot dilate to the same extent. When this secondary obstruction develops no further dilatation of the rectum occurs, but the pelvic colon becomes progressively larger, so that the erroneous impression may be gained that the rectum itself is unaffected.

Symptoms.—(a) *Hirschsprung's Disease.*—There is almost always a history of constipation dating either from birth or from the first few months of life. At an early stage the bowels cease to act spontaneously, and drugs gradually lose their effect until an evacuation can only be procured by means of enemata. The stools are generally soft or even semi-fluid, but in early cases scybala may be passed. Soon after the onset of the constipation, the abdomen, which is generally normal at birth, begins to increase in size owing to distension of the colon with gas and faeces, the size varying from time to time according to the frequency with which the bowels are opened. By examining the patient with the X-Rays after a barium meal it is possible to recognise where the stasis begins, and if a barium enema is also given the exact extent of the dilatation can be discovered. The rectum is greatly dilated and filled with faeces, which are generally quite soft, unless secondary obstruction has developed at the pelvi-rectal flexure, when the rectum is empty, and a mass of faeces may be felt in the pelvic colon through its anterior wall. With proper treatment the patient can lead an ordinary life and has no symptoms of toxæmia. If neglected, enormous accumulations of faeces collect. Formerly, before the true nature of the condition was recognised, the bowels sometimes ceased to act at all and death often occurred from chronic faecal obstruction. This should now never occur.

(b) *Megacolon in Adults.*—When a megacolon is discovered in adults, it is generally impossible to decide whether it dates from early childhood or whether it is a result of anal achalasia developing at a later date. It may give rise to no symptoms beyond a mild degree of constipation. The abdomen is often not obviously distended, though the diaphragm is pushed up by the dilated bowel. Acute attacks of violent pain due to temporary obstruction may occur ; they generally end spontaneously after a few hours and are probably caused by a partial volvulus of the dilated pelvic colon. After an opaque meal the large intestine as far as the descending or iliac colon is seen ; it is then lost in the enormous pelvic colon. In order to define the position of the latter an opaque enema of six or eight pints is required. A large gas-containing loop is seen under the left dome of the diaphragm, which may be pushed so far up that the heart is displaced to the right. As the intestinal symptoms are sometimes quite latent, the condition has often been mistaken for the rare primary abnormality of the diaphragm, which

gives rise to so-called eventration of the diaphragm. In other cases the dilated pelvic colon can be seen with the X-Rays above the liver under the right lobe of the diaphragm. The sigmoidoscope can be passed its full length without meeting the slightest resistance, and the walls of the enormous cavity formed by the pelvic colon can then be seen. As a rule the mucous membrane is healthy, but in neglected cases chronic inflammation and ulceration may occur, and I have seen two cases in which a carcinoma had developed.

Treatment.—All cases of Hirschsprung's disease and of megacolon in adults can be kept in a satisfactory state of health by non-surgical means, though naturally the dilated and hypertrophied colon only rarely contracts to a normal size. Such operations as colostomy, ileo-sigmoidostomy and colectomy, which were formerly practised in these cases, had a very high mortality and rarely led to any appreciable improvement, as the primary seat of obstruction, the anus was left untouched. The only exception is in the rare cases in adults in which it may become necessary to remove a single loop of the pelvic colon which has formed a chronic volvulus and gives rise to attacks of acute pain from partial obstruction. Recently lumbar sympathectomy has been performed with the object of reducing the tone of the anal sphincter, but this object can be very much more simply attained by local treatment. The anal sphincter should be gradually dilated by means of a vulcanite conical bougie or by a thick-walled rubber flatus tube of large diameter, which is kept in position for a quarter to half an hour before defæcation at first every morning and later at intervals of increasing length. In many cases regular action of the bowels without the aid of aperients or enemas results, and the use of the instrument can often be discontinued after a time. In some cases defæcation is never complete, and a weekly saline enema is required to prevent an accumulation from forming. It is, moreover, often necessary to give a series of enemas to remove a large accumulation before beginning treatment, and occasionally this can only be accomplished digitally under general anæsthesia. Paraffin should be given to keep the stools soft, but aperients are rarely required.

A. F. HURST.

ACUTE INTESTINAL OBSTRUCTION

Acute intestinal obstruction is a condition in which the passage of the contents along the intestinal canal is more or less suddenly obstructed either completely or in greater part. Only mechanical causes of intestinal obstruction will be dealt with in this place, conditions of paralysis or spasm causing obstruction being considered elsewhere.

Ætiology.—The causes of acute intestinal obstruction are numerous, and may best be considered under (1) causes within the lumen of the bowel, (2) causes in the wall of the bowel, and (3) causes outside the bowel, while there are two additional conditions—intussusception and volvulus—which do not come under any of these categories.

1. Causes within the lumen of the bowel giving rise to acute obstruction are gall-stones, fecal accumulations, and, very rarely, true foreign bodies.

Large gall-stones enter the intestine through a fistula between the gall-bladder and duodenum or, more rarely, some other part of the intestinal canal.

Gall-stones are generally passed spontaneously ; when this does not occur the site of impaction is nearly always the lower part of the ileum near the ileo-cæcal sphincter.

Fæcal accumulation is a common cause of an acute termination to a case of chronic obstruction, but even without any previous narrowing it may cause obstruction. In such case the fæcal mass may be enormous in size and of a stony hardness ; it leads more frequently to the pseudo-diarrhœa of partial obstruction than to complete obstruction.

2. Causes in the wall of the bowel give rise in most cases to chronic rather than acute obstruction ; the commonest of such narrowings are those due to cancer. These conditions are discussed elsewhere, and it is only their liability to an acute termination which needs consideration here. Such a final catastrophe may result from the impaction of fæces, a distended coil of bowel may become twisted, or acute paralysis of the intestinal wall with or without peritonitis may develop. Congenital stricture is a rare cause of acute intestinal obstruction in early infancy ; apart from stricture of the rectum, the commonest site is in the duodenum, just above the entrance of the bile-duct, and in connection with Meckel's diverticulum.

3. The most common cause outside the intestine is strangulation of a portion of intestine by congenital or adventitious bands, diverticula or peritoneal adhesions. Such bands may result from old tuberculous or inflammatory disease, or may be a sequel to a laparotomy, if blood is left in the peritoneum or the peritoneum is much damaged. They may be produced by the adherence of normal structures, such as the omentum, Fallopian tube or appendix to other abdominal organs, or may result from the presence of a persistent Meckel's diverticulum. The latter may remain attached to the umbilicus, or its free end may become adherent. Such bands may obstruct by bridging across a portion of bowel, or a knuckle of bowel may become twisted round or under them, or, if the band is not long, mere kinking at its point of attachment may be sufficient to obstruct the lumen. Internal hernias may give rise to strangulation and intestinal obstruction ; their commonest sites are congenital or acquired slits or tears in the mesentery, or omentum, one or other of the normal peritoneal fossæ, or, more rarely, the foramen of Winslow or congenital or acquired apertures in the diaphragm. The peritoneal fossæ into which such internal hernias may pass are situated in the neighbourhood of the duodeno-jejunal flexure, in the peri-cæcal region, and in the root of the pelvic mesocolon.

4. *Intussusception*.—By intussusception is meant the passage of one segment of intestine into another immediately below. When this occurs a tumour is formed consisting of three layers, the outermost or intussusciens being the portion of bowel into which invagination is occurring, and the inner two constituting the intussusceptum, which therefore consists of an entering layer and a returning layer. Between these latter is the strangled mesentery, interference with the vessels of which speedily occurs and induces changes in the intussusceptum. The apex is the distal part of the intussusception, and the neck the narrow part where the returning layer turns to become the sheath or intussusciens.

The chief cause of intussusception is undue enlargement of the intestinal lymphatic tissue producing irregular muscular action, aided no doubt by an unusually long mesentery, and by an atonic condition of the ileo-cæcal

sphincter. All these three factors, particularly the first, are most common in early childhood, and intussusception is consequently rare at other ages; 70 per cent. of cases occur in infants under a year old. In adults an intestinal polypus or carcinoma is often the starting-point of the invagination, which generally differs from that occurring in infants by being chronic instead of acute.

Various forms of intussusception occur, of which the ileo-cæcal variety, with the ileo-cæcal valve as its apex, constitutes about 70 per cent. Enteric, colic, ileo-colic and multiple intussusceptions are less frequent. An intussusception always increases at the expense of the ensheathing layer, its apex remaining constant.

5. *Volvulus* is a condition in which a coil of intestine becomes twisted on itself around its mesenteric axis, leading to interference with its circulation and with the passage of its contents. It occurs most frequently in the pelvic colon and the ileum, but may affect the cæcum or any part of the intestine with a mesentery. It usually occurs late in life, is commonest in males, and depends partly upon an abnormally shaped mesentery and partly upon loading of the loop from chronic constipation. The dilated coils above a chronic obstruction are especially liable to become twisted and so bring about an acute termination to the case.

Pathology.—In acute intestinal obstructions the conditions found fall mainly into two groups depending on (1) the occurrence of obstruction of intestine with a previously normal lumen, and (2) acute obstruction terminating a case of gradually increasing chronic obstruction.

1. In most cases in this group a portion of intestine is strangulated in addition to the obstruction to the lumen of the bowel, and consequently the condition of the intestine must be considered in three regions—namely, above the obstruction, below it, and in the strangulated coil itself. An exception occurs in the acute obstruction produced by an impacted foreign body, where, of course, there is no strangulation.

(a) The intestine above an acute obstruction is usually greatly distended, its walls are at first pale and thin, and later cedematous and purple in colour, and the extent of these changes rapidly increases upwards as the obstruction persists. The distended coils are full of fluid (partly the normal dammed-back secretion, partly an exudation of serum), and as the case progresses bacteria escape through the distended and paralytic coils, and lead to peritonitis. These changes are far more marked in small intestine obstruction than when the colon is affected.

(b) Below the obstruction the coils are, as a rule, empty, contracted and pale.

(c) As a result of circulatory interference, the strangulated coil itself becomes distended with effused blood and gas, the latter mainly CO₂, which cannot be absorbed. It is purple in colour, tense, cedematous and paralysed, and it exudes bloodstained fluid both into its lumen and into the surrounding peritoneum. If the strangulation is sufficiently severe to obstruct arteries as well as veins the coil becomes gangrenous in less than an hour. Such a coil is grey and loses its peritoneal sheen; it is flaccid and exudes free gas and stinking fluid into the peritoneum. This condition is, of course, irrecoverable, but in less complete strangulation the intestinal wall quickly returns to normal when the strangulation is released. A strangulated coil soon loses power to prevent the passage of bacteria, and if left alone its

vessels inevitably become thrombosed, and its walls become gangrenous and ultimately perforate. The contents of an obstructed loop are profoundly toxic, the toxicity being greater the higher in the course of the alimentary canal the obstruction is situated.

2. When acute supervenes on chronic obstruction, the bowel has already had time to accommodate itself in some degree to the presence of narrowing of its lumen. The final blockage of the passage is most frequently due to impaction of fæces in the narrowed part, or kinking, adhesion, volvulus or acute paralysis of the intestine above it. In such cases the already existing hypertrophy above the obstruction gives place to rapidly increasing distension, and as a result the intestinal circulation is interfered with, and gas, being no longer efficiently absorbed, collects within the bowel. The enteritis and ulceration usually present in some degree above a chronic obstruction rapidly increase, and perforation and consequent peritonitis speedily follow.

Symptoms.—The symptoms of acute intestinal obstruction vary to a certain extent with the particular cause of the condition, but some of them are present in all cases. Of the general symptoms, pain, vomiting, constipation and collapse are the most important.

Pain is an early symptom and is very severe, in many cases a patient in perfect health being suddenly seized with an acute abdominal pain which doubles him up and never remits. At first the pain is stabbing in nature, but later he complains of exacerbations which are colicky in character, and which occasionally serve to localise the obstruction. If the case is allowed to progress until peritonitis supervenes, the continuous pain and tenderness associated with that condition are present in addition.

Vomiting, preceded by nausea and severe retching, usually comes on about an hour after the pain, but it may be delayed for 8 or 10 hours. Once it has begun it continues with increasing frequency, and from the second to the fourth day it becomes fæcal in character. The higher the site of the obstruction is situated in the bowel, the greater the vomiting and the sooner it becomes fæcal. Fæcal vomiting is not due to antiperistalsis, but is caused by the stagnant and excessive secretions of the portions of bowel above the obstruction, gradually extending upward until they overflow into the stomach and cause vomiting. The fæcal character is accounted for by the remarkable speed with which *Bacillus coli* and other organisms multiply in the stagnant contents.

Collapse is early and severe. The patient is prostrated, anxious, and restless, the pulse is rapid, small and thready, the temperature subnormal, and the extremities cold and clammy. The collapse is partly reflex from stimulation of the vagal and splanchnic nerve endings in the abdomen, and is partly due to loss of fluid from sweating and excessive intestinal secretion. A very important part is also played by the toxic intestinal contents; the higher in the bowel the obstruction is situated the greater is the toxicity of the stagnating contents.

Constipation is as a rule absolute, although the bowel below the obstruction may empty itself shortly after the onset of the pain and vomiting. Neither fæces nor flatus are passed, and enemata after washing away any fæcal material present in the bowel below are either retained or return slowly without force.

In addition to these cardinal symptoms the patient presents certain other important signs. The tongue is dry and the teeth are covered with sordes. The abdomen at first is not tender to touch, and sometimes pressure may relieve the pain. It is often not distended, though in some conditions, such as volvulus, the distension may be extreme. If acute obstruction supervenes on chronic obstruction visible peristalsis may be present, and the coils can be felt to harden under the hand. Occasionally a tumour is felt in the abdomen, especially in intussusception, where a sausage-shaped mass can frequently be felt. On auscultation intestinal sounds are present in increased intensity. If the case goes on until peritonitis supervenes the symptoms of that condition develop and consequently the abdominal picture changes. In acute intestinal obstruction the urine is scanty and highly coloured, and when the obstruction is low in the bowel it contains a great excess of indican. The viscosity of the blood is increased from loss of fluid; this probably accounts for the frequent cramp-like pains in the limbs.

Diagnosis.—The diagnosis of acute intestinal obstruction is usually easy, but the further differentiation of the site and nature of the obstruction, though sometimes fairly simple, is often impossible before operation. The history is of importance in deciding whether the acute symptoms have supervened on those of chronic obstruction, in which case similar but less severe attacks which were relieved by enemata or purgatives may have occurred. A previous history pointing to gall-bladder trouble, particularly if the onset of obstruction is somewhat less acute than usual, suggests gall-stone impaction.

Inquiry should be made for evidence of abdominal attacks suggesting appendicitis, salpingitis, or other conditions, which might produce bands.

The presence in an infant of a sausage-shaped tumour, which can be felt to harden and is situated usually in the upper abdomen, with tenesmus and the passage of blood and slime, acute attacks of colic causing the child to scream and to draw up its legs, with occasional vomiting, forms a characteristic picture of intussusception, and enables a confident diagnosis to be made in many cases. In doubtful cases, examination under anaesthesia may be required, and rectal examination may enable the intussusception to be felt.

In volvulus the onset is acute, but collapse may be absent. Vomiting is not frequent at first, but the characteristic feature is the rapid onset and extreme degree of distension. This distension may at first be localised and indicate the seat of the volvulus, but it soon involves the whole abdomen and may cause severe cardiac and respiratory embarrassment.

Distension implies interference with the blood supply and consequent deficient absorption of gas from the bowel; it is thus a valuable indication as to whether strangulation has taken place as well as intestinal obstruction.

The conditions from which acute intestinal obstruction has to be differentiated are numerous. The most important is hernia, and a careful examination of the hernial apertures should always be made. In some cases of small femoral hernias in fat persons it is very easy to overlook the condition, and in the rare obturator hernia diagnosis is frequently only possible on opening the abdomen. Faecal impaction is another important condition to be considered, particularly in view of the grave results of laparotomy mistakenly undertaken for its relief. The history of chronic

constipation and the presence of hard or putty-like masses in the rectum or pelvic colon should prevent errors.

Peritonitis is often a source of difficulty. The extreme tenderness and rigidity, the absence of fæcal vomiting, the partial nature of the constipation at first, as well as the temperature, history, and silence of the abdomen on auscultation are distinguishing features. Difficulty may arise from conditions causing acute stimulation of the sympathetic nerve, such as torsion of the testicle, ovary, or omentum, or the passage of a renal or biliary calculus. Careful inquiry of the history, the characteristic distribution of pain in the colics, examination of the scrotum and vagina and of the urine will usually lead to a correct diagnosis. Further, in these conditions enemata generally result in passing of flatus, and the course of the disease does not follow the usual sequence of cases of acute intestinal obstruction. In acute pancreatitis the pain is localised in the epigastrium, while the constipation is usually not absolute.

Lead colic can be distinguished by the blue line on the gums, the history, the blood picture, the absence of fæculent vomiting, and the result of enemata ; while a routine neurological examination will distinguish tabetic crises.

Rare conditions which may lead to mistakes are embolus or thrombosis of the superior mesenteric vessels. In embolus some cardiac lesion is usually present, and in thrombosis there may be evidence of cirrhosis, gall-bladder disease or thrombosis of other veins, while hæmatemesis and melaena are common in both conditions.

Prognosis.—Spontaneous cure is remotely possible in all cases of intestinal obstruction, but in the majority of cases, if operation is not undertaken, death occurs at varying intervals, the average being after 6 days. Once the obstruction has been relieved by operation recurrence is uncommon, excepting perhaps in cases due to adhesions following operation. Even when operation is undertaken acute intestinal obstruction has a grave outlook, depending partly on the length of time elapsing before operation and partly on the nature of the lesion present. Volvulus is the most fatal form of obstruction, closely followed by gall-stone impaction. Other conditions materially affecting the prognosis are the age and general condition of the patient, and the presence of toxæmia, septicæmia, peritonitis, or complicating conditions elsewhere.

Treatment.—Excluding cases of fæcal impaction the treatment of all cases of acute intestinal obstruction is immediate operation. The object of the surgeon is to locate the seat of the obstruction, and to relieve it as quickly as possible with the minimum of handling and exposure of the abdominal contents. When the abdomen is opened a collapsed portion of gut is sought, as it helps to localise the seat of obstruction. When found, the obstruction must be relieved in the simplest possible manner, by reducing a hernia, dividing a band, reduction of an intussusception by manipulation, removing a gall-stone, etc. If, however, the obstruction cannot be relieved, or if the bowel is too severely damaged to return to the abdomen, it is wise simply to establish drainage above the obstruction and to wait till the acute period is passed before undertaking further measures. In cases with much distension, where the obstruction is obviously in the colon, and where an exploration would entail considerable handling, the proper treatment is undoubtedly to perform a blind cæcostomy and to delay further procedures

until the distension has been relieved. Apart from operation, saline solution should be given intravenously, or subcutaneously to combat the fluid loss, and opium may be given to relieve pain once the diagnosis is established and operation agreed to. Anti-gas gangrene serum (*B. welchii*) is of value in combating toxæmia, and helps to relieve distension. It should be given intramuscularly, the initial dose being 25 c.c., followed by 10 c.c. on the two next successive days.

APPENDICITIS

Ætiology.—The two sexes are affected equally. No age is exempt, but whereas acute appendicitis is more common in children, chronic appendicitis is more common in adults.

The appendix may become infected either by organisms spreading from the lumen of the cæcum or conveyed by the blood. In the former case, the original infection may presumably come from infected food, but septic foci in connection with the teeth, tonsils and naso-pharynx are undoubtedly of more importance. The latter are also the chief sources of hæmatogenous infection.

The commonest organism is the *Bacillus coli communis*; next in order of frequency come streptococci and staphylococci. The proteus, tubercle and actinomycosis organisms are rare. Congenital or acquired abnormalities are present in a considerable proportion of cases. In the former the appendix is not fully descended, is of the infantile variety, or is twisted on itself. In the latter, there are adhesions or kinks caused by previous inflammation either of the appendix itself or of neighbouring organs; and in many cases the bands resulting from chronic intestinal stasis lead to kinking of the appendix. Obstruction to its lumen from any of these causes produces stagnation of its contents, and provides the necessary conditions for bacterial invasion. Foreign bodies are another cause, but they occur less frequently than might be expected. Intestinal worms, pins, and fruit pips and stones have all been met with, but by far the commonest foreign body is the so-called "appendicular concretion," formed of inspissated faecal material moulded into shape by the appendix itself.

ACUTE APPENDICITIS

Pathology.—In catarrhal appendicitis the mucosa only is affected, but in the commoner diffuse type all the coats are involved, the organ being hyperæmic, rigid, tense, and swollen, and the mucous membrane being frequently ulcerated. Later the lumen of the appendix becomes filled with pus, and if there is obstruction, empyema of the organ results. Later still, local or general gangrene occurs, the most frequent sites being the tip or the base. Perforation is very liable to take place at any of these stages, leading either to a localised appendicular abscess or to generalised peritonitis. The chief factor in determining which of these two complications will occur is the virulence of the organism, since it requires time for the reaction of the peritoneum to come into play sufficiently to localise the results of perforation to the immediate neighbourhood. If the lumen of the appendix is obstructed by a stereolith, acute appendicular obstruction results, and the tension of decomposing faecal matter within its lumen leads to rapid gangrene and perforation.

In milder cases the inflammation tends to resolve, and the appendix may return to an apparently normal condition, but if the attack has been at all acute, either adhesions or narrowing of the lumen generally remain, leaving it far more liable to further attacks of inflammation. If perforation and abscess formation occur and operation is not undertaken, spreading peritonitis results. Suppurative pylephlebitis may result from spread of infection along the mesenteric veins either with or without perforation of the appendix.

Symptoms.—In nearly all cases the following symptoms are present, though they may vary in degree—(1) sudden abdominal pain, (2) pyrexia, (3) increased pulse rate, (4) gastro-intestinal symptoms, (5) local signs.

1. *Sudden abdominal pain.*—The onset is usually sudden, the patient being seized with severe abdominal pain, often severe enough to produce collapse and vomiting, and often referred at first to the region of the umbilicus, particularly in children. Later the pain becomes more or less localised to the right iliac fossa, and may be of considerable intensity. In the obstructive type of case, colicky pain marks the onset, unassociated with fever or increase of pulse rate, and continues until perforation results, or operation is undertaken. In very severe cases, especially in children, and where early gangrene occurs, the pain may be comparatively slight after the initial onset, and in other cases the affection may progress to abscess formation with relatively little pain. Such cases are, however, the exception, and the pain is usually a prominent symptom.

2. *Pyrexia* is almost always present at some time during the attack, except in cases of the obstructive type, where its absence is apt to lead to mistakes in diagnosis, but its height is no measure of the severity of the lesion in the appendix. There is sometimes a rigor at the onset, and the temperature in an average case varies from 100° to 102° , rarely higher. A rise only to 99° or 100° is not uncommon, but is important, as very few cases occur in which there has not been some pyrexia at some period of the attack. When a localised abscess has formed, and in very severe cases with perforation and generalised peritonitis, the temperature may be normal or subnormal throughout.

3. The *pulse rate* is usually increased and tends to continue to increase as the disease progresses. In cases of appendicular obstruction there may be no increase in the pulse rate until perforation has occurred.

4. *Gastro-intestinal disturbances* are almost invariably present. The tongue is furred and rapidly becomes dry. Vomiting is frequent. There is usually vomiting at the onset of the attack, and though this persists in the severe cases with peritonitis, it may pass off, but nausea usually continues. Constipation is the rule, and in the majority of cases is absolute. Diarrhoea is, however, by no means uncommon, indicating usually a pelvic position of the appendix, in which the inflammation spreads to and irritates the rectum. If the process is allowed to progress, complete constipation resulting from peritonitis and consequent paralysis of intestinal movements ensues. Even before this stage has been reached, auscultation over the region of the cæcum often reveals a complete absence of the usual intestinal sounds, which may be of considerable help in diagnosis.

5. *Local signs.*—There is usually no distension of the abdomen at the onset of the attack, but on inspection it will be seen that the lower abdomen moves less freely than the upper on respiration, and the right side less than

the left. There is frequently hyperæsthesia of the skin in the right iliac fossa, and occasionally some cedema can be discovered by loosely picking up the skin and subcutaneous tissues between the fingers and comparing with the other side. There is great rigidity of the right rectus muscle, and this is probably the most important single sign; the rigidity is often too great to allow of any proper deep palpation. In addition to the rigidity there is great tenderness and pain on palpation, which has its maximum at MacBurney's point, situated at the junction of the outer and middle thirds of a line drawn from the anterior superior iliac spine to the umbilicus. In children the maximum pain and tenderness are often in the region of the umbilicus. In some cases an ill-defined mass can be felt in the right iliac fossa, and the longer the history, the more likely is such a mass to be present. It is constituted mainly of adherent coils of intestine and omentum surrounding the inflamed or perforated appendix. Rectal examination is often of value, and in many cases a tender mass can be felt on the right side of the rectum, when none can be made out from above. Considerable irritability of the bladder may be present, especially with a pelvic appendix, and the urine, which is scanty, frequently contains albumin.

A blood count is occasionally of value for purposes of differential diagnosis, and usually shows a leucocytosis of from 15,000 to 20,000.

In many of the worst cases, some or all of these signs and symptoms may be absent, but with a careful examination and a clear history it is usually possible to reach a correct diagnosis.

In some cases an abnormally situated appendix gives rise to characteristic symptoms. With a retro-cæcal appendix, local signs in the right iliac fossa may be absent, there being instead great pain and tenderness in the loin, and rigidity without great tenderness of the right rectus. These cases are specially apt to develop subdiaphragmatic abscess, and later empyema. An appendix running down into the pelvis is apt to give diarrhœa and bladder irritability, local rigidity may be slight and a mass can usually be felt per rectum. An appendix running directly inwards may occasionally give rise to left-sided symptoms.

Course.—Where a correct diagnosis is made, early operation should be undertaken at once, for reasons to be discussed later, but if for any reason operation is delayed the case may take one of three possible courses.

(a) Gradual recovery may ensue, and in first attacks this will occur in a large number of cases. Improvement begins about the second or third day and the acute symptoms generally subside in a week. In such cases the patient is extremely liable to have further attacks, a liability which is increased in proportion to the degree of change which has occurred in the appendix.

(b) In many cases, as the result of ulceration or perforation of the appendix, the local symptoms not only do not disappear at the end of the first week, but persist and become aggravated. The temperature usually rises and there may be rigors, while at the same time a tumour becomes palpable in the iliac fossa. In some cases the abdominal wall may become cedematous and indurated, and the patient frequently begins to lose weight rapidly, to sweat profusely and to show all the signs of closed suppuration. If an operation be now performed, an abscess is found in connection with the appendix, having definite walls composed of adherent and matted intestine,

omentum and parietal peritoneum. Such abscesses often contain large quantities of very foul-smelling pus, and if left alone may burst into the rectum or general peritoneum, or more rarely on to the surface, usually in the neighbourhood of the umbilicus. Spontaneous recovery may follow rupture into the rectum or on to the surface, but in the other cases death is almost certain to ensue.

(c) The third result of an unoperated attack of acute appendicitis, and by far the commonest cause of death in this disease, is generalised peritonitis. This may occur either from perforation of the appendix before limiting adhesions have had time to form, as in cases of the obstructive type, or it may occur without any perforation at all. In the latter case bacteria pass through the wall of the inflamed appendix and set up suppuration in the neighbourhood; if the resistance is poor, this involves the neighbouring peritoneum and ultimately leads to a generalised infection. In other cases a localised abscess may form and later burst into the peritoneum, a result often precipitated by sudden exertion on the part of the patient, injudicious palpation, or the administration of aperients. The great danger of appendicitis, and one that can only be met by immediate operation in all definite cases, is that general peritonitis may occur from the very beginning, and its symptoms may be indistinguishable from those of the acute appendicitis itself. In the hands of competent abdominal surgeons, operation in the early stages is one of almost absolute safety, and in these circumstances any delay, with the shadow of possible peritonitis menacing the patient at any time, is quite unjustifiable.

Diagnosis.—As appendicitis is by far the commonest acute inflammatory condition occurring in the abdomen in people under middle age, it must always be thought of in the presence of acute abdominal disease. In a typical case, with acute onset of abdominal pain, generalised at first and later settling into the right iliac fossa, with vomiting, constipation and local rigidity and tenderness, the diagnosis is easy, but one or more of these signs may be absent, and in such cases it is well to remember that a single positive sign is worth several negative ones. The most constant single sign is tenderness on deep pressure in the iliac fossa, and if this is present even in moderate degree, the case must be carefully watched before a diagnosis of acute appendicitis can be safely discarded.

Rectal examination may reveal bulging of the rectal wall by an abscess, particularly with a pelvic appendix, which, if palpable, is extremely tender.

A general examination of the patient is essential in order to eliminate certain other conditions which sometimes lead to mistakes. Right-sided pneumonia may cause difficulty, as the onset is sometimes associated with considerable pain and rigidity in the right side of the abdomen, but as a rule the accompanying respiratory symptoms and signs, especially the rapid respiration, will prevent error. In children contraction of the right psoas muscle with flexion of the hip may suggest an acute arthritis or even a psoas abscess, whilst a psoas abscess is occasionally mistaken for appendicitis. Of the abdominal lesions most likely to cause confusion the most difficult to differentiate is acute tubo-ovarian disease in women. In some of these cases, appendicitis coexists from spread of infection, and where doubt remains after a thorough pelvic examination it is safer to operate than to risk leaving a possible acute appendicular lesion.

In perforation of gastric or duodenal ulcers, the general shock is more profound, the rigidity is more general and board-like, and the pain is diffuse and not localised; in biliary, renal, and intestinal colic, the nature and distribution of the pain usually suffice to prevent mistakes. Twisting of a small ovarian cyst may be impossible to differentiate, but operation is called for in either case. In certain cases of typhoid fever the clinical picture may simulate appendicitis very closely. The relatively slower pulse and higher temperature, the constant headache, and the absence of any definitely acute onset, are of the greatest help in distinguishing, and a leucocyte count may be of considerable assistance, as leucopenia is present in typhoid fever in contrast with the leucocytosis of appendicitis.

Prognosis.—If left alone a considerable proportion of cases of acute appendicitis tend to recovery, but it is at present impossible to give an accurate prognosis of the course of any particular case within the first 48 hours. The chief cause of death is peritonitis, and less often pylephlebitis, septicæmia, or pulmonary embolism. Even if recovery from a first attack does occur, the patient is left with a far greater liability to subsequent attacks, and is in some danger of acute or chronic obstruction from the adhesions which so frequently develop. Successive attacks of appendicitis tend to be more severe, and a patient who has had two is almost certain to have further trouble.

With early operation the prognosis is extremely good, death being rare after operation within 36 hours. Even when operation is undertaken later in the attack, the prognosis is still good, unless general peritonitis has ensued, in which case the prognosis without operation is uniformly bad. A further great advantage of early operation is that drainage of the abdomen can be avoided in these cases, whereas in later operations drainage is frequently necessary with a consequent increased risk of post-operative hernia.

Treatment.—In acute appendicitis operated on within 36 hours of the onset, the mortality in the hands of most surgeons is negligible, and since it is quite impossible to determine the course which any particular attack is going to take, there can be no doubt that when the diagnosis is definitely established, operation should be undertaken at once. Some surgeons are of opinion that when the case is seen later than 48 hours from the onset and is tending to improve, medical treatment should be undertaken until the attack has subsided, and the appendix should be removed during the quiescent period. Since operation in these cases is, with modern technique, very little more difficult or dangerous than in early cases, such a view has little to recommend it, since it condemns the patient to two tedious periods of sickness instead of one, and there is, in addition, the risk of the patient's natural objection to an operation, when he feels perfectly well, overcoming the advice he has been given and leaving him exposed to all the risks of a further attack. When peritonitis or localised abscess formation has occurred, there are no two opinions as to the necessity of operation. If, for any reason, operation is impossible or refused, the patient should be kept in the Fowler position, should have nothing but water by mouth, and may be given morphine to diminish both pain and intestinal movement, provided always that the question of operation has been finally and definitely decided. Under no circumstances should a purge be given, as there can be no doubt that in far too many cases purgation is the direct cause of perforation.

Where an appendicular abscess has developed, it was formerly held that the abscess should be drained and the appendix removed subsequently. Modern surgical opinion is in favour of doing both at one operation, and in the hands of an experienced operator this procedure is undoubtedly best, but where skilled surgical aid is not available, simple incision and drainage of the abscess meet the immediate emergency.

E. G. SLESINGER.

CHRONIC APPENDICITIS AND APPENDICULAR DYSPEPSIA

Symptoms.—Chronic appendicitis may give rise to gastric symptoms, which may either be the sole manifestation of the disease, or may be accompanied by constant discomfort or short attacks of pain in the right iliac fossa. Epigastric pain, which may radiate downwards to the umbilicus or below, and occasionally towards the right iliac fossa, occurs after meals. The time of its onset is very irregular. Most commonly it occurs immediately after meals, but occasionally it may be delayed for 2 or 3 hours. It is at the most only slightly relieved by alkalis, and food rarely gives even momentary relief. It is aggravated by fatigue to a greater extent than is the case with the indigestion of gastric and duodenal ulcer and gall-bladder disease. The degree of discomfort varies from time to time; it is rarely completely absent, and may sometimes be sufficiently severe for the patient to go to bed. Nausea is common and is often present in the absence of vomiting. Vomiting may occur, especially after food and when the pain is severe, but it gives much less relief than in gastric ulcer. Heartburn and acid regurgitation are uncommon. Hæmatemesis may occur from an acute gastric or duodenal ulcer secondary to the appendicular infection, which is also occasionally associated with a chronic gastric or duodenal ulcer.

A fractional test-meal shows that in only 12 per cent. of cases gastric secretion is unaffected; in 55 per cent. of a series of 65 cases, in most of which the symptoms were mainly epigastric, there was hyperchlorhydria, and in 33 per cent. of cases, in most of which the pain was situated chiefly in the right iliac fossa, achlorhydria was present. Both the hyperchlorhydria and achlorhydria precede the development of the appendicitis. The hyperchlorhydria is constitutional and predisposes to the appearance of reflex gastric symptoms in the presence of any chronic abdominal disorder, such as chronic appendicitis. The achlorhydria, which is generally a result of chronic gastritis and is therefore curable, predisposes to the development of chronic appendicitis by leading to intestinal infection as a result of the absence of the antiseptic action of the normal gastric juice.

Tenderness is generally more marked in the right iliac fossa than in the epigastrium, even when there is no spontaneous pain in the former situation. Occasionally the localised tenderness can only be discovered when pressure is exerted directly over the appendix after it has become visualised with the X-Rays. In many cases pressure in the right iliac fossa leads to no local pain, but to discomfort in the epigastrium, sometimes with nausea, exactly simulating the spontaneous symptoms. Constipation is commonly present. In rare cases there may be chronic diarrhœa, but more frequently a form of pseudo-diarrhœa is present, in which frequent small stools are passed owing to irritation of the rectum caused by a chronically inflamed appendix situated

in the pelvis. Pelvic appendicitis may also lead to irritability of the bladder with frequent micturition, and in women to dysmenorrhœa.

Diagnosis.—The diagnosis of chronic appendicitis may be exceedingly difficult, and it is consequently a very common occurrence for an appendix to be removed without benefit. An operation is not justifiable for chronic appendicitis, unless the diagnosis has been confirmed by means of the X-Rays and, if possible, by Bastedo's inflation sign. The X-Rays show where the appendix is in almost all normal individuals and about 80 per cent. of cases of appendicitis, and its discovery in the pelvis or immediately under the liver may explain anomalous symptoms. In chronic appendicitis, the appendix itself or some part of it, especially the base or the tip, is always found to be the point of maximum tenderness, definitely more tender than the end of the ileum or the cæcum. By manipulating the cæcum so that the position of the appendix in the abdomen is altered, the tender point moves with it. In some cases pressure on the appendix produces epigastric discomfort, either with or without local tenderness. Indirect evidence of appendicitis is occasionally afforded by the presence of ileal stasis, and by the recognition of adhesions in the right iliac fossa, which are most commonly due to chronic appendicitis.

On inflating the colon with air through a tube introduced into the rectum normal individuals feel a generalised discomfort in the abdomen. Bastedo's sign of chronic appendicitis is the production under these conditions of localised pain in the right iliac fossa with increased tenderness, sometimes associated with or even entirely replaced by epigastric discomfort. This is present in a large proportion of cases, but never in salpingitis, ureteral calculus, gall-bladder disease or other conditions, which might simulate chronic appendicitis. Inflation should be carried out during the X-Ray examination, as it raises a pelvic cæcum and brings the appendix within reach of the palpating fingers. It also unravels confusing pelvic shadows and makes it possible to decide to what extent adhesions are present in connection with the terminal ileum, cæcum and appendix. If inflation fails to raise a pelvic cæcum and appendix into the abdomen, the X-Ray examination should be repeated with a full bladder, which always brings them within reach of abdominal palpation except in the very rare cases in which they are fixed in the pelvis.

If repeated attempts fail to visualise the appendix it is probable that its mouth is obstructed; in the presence of suspicious symptoms and tenderness in the ileo-cæcal angle the absence of an appendicular shadow favours the diagnosis of appendicitis. In such cases Bastedo's sign is also negative, as it depends upon distension of the appendix itself, which is only possible when barium can enter it.

Treatment.—Simple dietetic treatment gives little or no relief; this is an important point in diagnosis, as in any case of chronic dyspepsia, which does not yield to ordinary treatment, the possibility of chronic appendicitis should be considered. In mild and doubtful cases the effect of removal of any source of infection in the teeth and tonsils should be tried. In cases associated with achlorhydria the latter should be overcome by treatment of the gastritis if it is secondary, or by hydrochloric acid if it is primary, as this occasionally results in complete disappearance of the symptoms.

Recovery should follow the removal of the appendix, but it is not infrequent for the symptoms to persist for a time after the operation, especially if the

disease is associated with some functional nervous disorder or with chronic gastritis, gastric or duodenal ulcer, chronic typhlitis or chronic cholecystitis. Such associated conditions require attention both before and after the operation, and if the gall-bladder is infected it should be removed at the same time.

ARTHUR F. HURST.

DISEASES OF THE LIVER

TESTS FOR HEPATIC FUNCTION

In our experience the lævulose test for hepatic efficiency is the only one of sufficient value to deserve description. In considering the diagnosis of jaundice van den Bergh's reaction for excess of bile-pigment in the blood will be described, and the direct investigation of the bile obtained by means of a duodenal tube will be considered in connection with cholecystitis.

Lævulose tolerance test.—50 grm. of lævulose are taken in 100 c.c. of water on an empty stomach: the blood sugar is estimated immediately before and 1 and 2 hours later. A first hour elevation of 30 mgrm. or a second hour elevation of 15 mgrm. per 100 c.c. is positive, and a first hour rise of 25 mgrm. or a second of 10 mgrm. is suspicious evidence of hepatic insufficiency; a first hour elevation of 25 mgrm. with a second hour elevation of 10 mgrm. is also positive evidence. If the fasting blood sugar is between 100 and 120 mgrm. these figures can be reduced by 5 mgrm. If it is below 80 mgrm. or all the figures are above 120 mgrm. no definite conclusions can be drawn from the test (Kimball).

JAUNDICE

Synonym.—Icterus.

Definition.—Jaundice is the condition caused by the presence of bile-pigment in the blood, which manifests itself clinically by yellow coloration of the conjunctivæ and skin.

Ætiology and Pathology.—All cases of jaundice may be divided into three groups—hæmolytic jaundice, toxic and infective hepatic jaundice, and obstructive jaundice (McNee).

(a) **HÆMOLYTIC JAUNDICE.**—In hæmolytic jaundice bilirubin is produced from hæmoglobin set free in the general circulation by the destruction of red cells as a result of abnormal fragility, as in acholuric jaundice, or of the presence of hæmolytic toxins in the blood. The hæmoglobin set free is broken down, and bilirubin is formed by the action of the endothelial cells of the spleen, and to a less extent the similar endothelial cells of Kupffer, which lie along the portal capillaries adjacent to the bile capillaries of the liver, and the endothelial cells of other organs. The excess of bile-pigment in the blood is thus formed quite independently of the glandular cells of the liver.

(b) **TOXIC AND INFECTIVE HEPATIC JAUNDICE.**—This includes the jaundice caused by the various conditions described under the heading of toxic and infective hepatitis on p. 672. In septicæmia and other toxic and infective

conditions the jaundice may be either hæmolytic or hepatic in origin or both.

Toxic and infective jaundice is due in part to damage to the hepatic cells, which may vary from cloudy swelling in pneumonia, fatty degeneration in chloroform poisoning, and partial necrosis in spirochætal jaundice to almost complete necrosis in acute yellow atrophy. The damaged hepatic cells are unable to convey the bile-pigment from Kupffer's endothelial cells lining the portal capillaries into the bile capillaries; the pigment consequently passes to the hepatic vein and thence into the general circulation. At the same time any bile-pigment which is excreted by still active liver cells is obstructed by inflammatory swelling of the walls of the small bile-ducts caused by toxins excreted in the bile; it is consequently reabsorbed. The jaundice is thus in part due to insufficiency of the hepatic cells and in part obstructive, the proportion of the two factors varying in different cases. The degree of hepatic insufficiency can be judged by the lævulose test, which is unaffected in pure obstructive jaundice.

(c) OBSTRUCTIVE JAUNDICE.—In obstructive jaundice bile excreted by the hepatic cells is reabsorbed by the hepatic blood capillaries together perhaps with the lymphatics, owing to the rise in pressure caused by obstruction of the bile-ducts. The obstruction may occur (1) within the ducts, or it may be due to (2) changes in their walls or (3) pressure from without.

1 *Obstruction within the ducts.*—This is almost always due to gall-stones. In very rare cases a hydatid cyst has ruptured into a duct, which becomes obstructed by a piece of membrane or a daughter cyst, or a round worm has entered the common bile-duct from the duodenum.

2. *Obstruction due to changes in the walls of the ducts.*—Congenital obliteration of the bile-ducts is a rare cause of icterus neonatorum (p. 666). An acquired stricture may result from accidental injury of the common bile-duct during an operation, cicatrization of an ulcer produced by a gall-stone is excessively rare except in the cystic duct, where it does not lead to jaundice. Catarrhal jaundice is generally due to the obstruction produced by inflammatory swelling of the mucous membrane in the biliary papilla. Infective and suppurative cholangitis also lead to jaundice, but in some cases, at any rate, the obstruction to the ducts is associated with changes in the liver cells, which are in part responsible for the production of the jaundice. 3) Primary carcinoma of the hepatic and common bile-ducts and biliary papilla gives rise to jaundice at an early stage of its development.

3. *Pressure on the ducts from without.*—Malignant tumours of the liver, and very rarely gummata and hydatid cysts, give rise to jaundice by pressing on the intrahepatic branches of the bile-ducts; if some of the latter escape, bile still passes into the duodenum from other parts of the liver and the fæces remain coloured. The tumour may also project into the portal fissure and give rise to jaundice with colourless stools by pressing upon the hepatic ducts or common bile-duct.

4) Enlarged glands in the portal fissure may cause jaundice by pressure upon the ducts. The most common cause is primary or secondary cancer of the liver, as these glands drain the liver, but not the other abdominal viscera or peritoneum; for the same reason they rarely become tuberculous. They are very rarely enlarged in Hodgkin's disease and never in syphilis.

Jaundice may occur in cancer of the stomach, even when no

deposits are present in the liver or in the glands in the portal fissure; this is due to the pressure of glands in the neighbourhood of the head of the pancreas, or to direct spread of the growth into the lesser omentum, where it compresses the common bile-duct and may invade its walls.

Jaundice is produced by obstruction of the common bile-duct when chronic pancreatitis occurs in an individual in whom the duct is embedded in the head of the gland. It is generally present in cancer of the head of the pancreas, but very rarely with a pancreatic cyst or calculus. 7)

Symptoms.—Jaundice appears first in the conjunctivæ and then successively on the face, neck, body and limbs. The mucous membrane of the lips and palate becomes yellow very soon after the conjunctivæ. In chronic obstructive jaundice the pigment in the skin becomes dark green. In a small proportion of cases which have lasted for a very long period multiple xanthoma (or xanthelasma) develops, but this condition also occurs without jaundice. The patches are generally flat and are sometimes very painful: they consist of cholesterol, which the blood in jaundice contains in excess. They are most frequent in the eyelids, but in rare cases they are found in the hands and feet and even over the whole body. In chronic jaundice there is a tendency for telangiectases to develop over the body and face and occasionally on the mucous membrane of the tongue and lips; they may disappear at the same time as the jaundice. Purpura and hæmorrhage from mucous membranes, especially the nose and gums, may occur.

The urine becomes bile-stained before the conjunctivæ and skin, the interval being sometimes as long as 24 hours, but it generally returns to normal before the yellow colour of the skin has disappeared. The urine may be yellow, olive, dark brown or even black. The colour can be distinguished from that in urobilinuria, hæmaturia and melanuria, and that produced by rhubarb, senna, sautonin and chrysophanic acid by Gmelin's test for bile-pigment.

When obstruction to the bile-ducts is complete, no bile reaches the intestines and urobilin is absent from the urine; when the obstruction is incomplete decomposition of the bile which reaches the intestines may occur and urobilinuria results. Bile-salts are only present in the urine for the first few days. The disappearance is due to the fact that they are only produced in very small quantities, being constantly reabsorbed from the bowel and then re-excreted; when the bile-ducts are obstructed the kidneys rapidly excrete all the bile-salts present in the blood. In chronic obstructive jaundice bile-stained casts are almost always present in the urine, and less frequently albuminuria occurs. The urine often reduces Fehling's solution owing to the presence of glycuronic acid.

The fæces are bulky and often extremely offensive. When the obstruction is complete they are clay-coloured, owing partly to the absence of stercobilin and partly to the presence of excess of fatty acids and soaps which require the presence of bile for their complete absorption, and of neutral fat if the pancreatic duct is simultaneously obstructed (p. 714). Loss in weight results, and the excess of undigested food which reaches the colon is likely to cause excessive bacterial decomposition. This may lead to intestinal intoxication if the hepatic cells are damaged and their antitoxic action impaired in addition to the bile-channels being obstructed.

The sweat may contain bile, which is also sometimes present in the tears.

and in the milk; but the saliva, cerebro-spinal fluid and mucus of the alimentary canal are free from bile, although the salivary glands and other organs are deeply bile-stained. The sputum in pneumonia and the effusion in pleurisy and peritonitis contain bile-pigments. The blood plasma is tinged with bile. Coagulation is considerably delayed, perhaps owing to the fixation of the lime salts of the blood by the bile-pigment.

In jaundice of recent origin the pulse is slow, but in other cases it is generally normal; there may be an abnormal tendency to acceleration on assuming the erect position. The slowing is probably due to the bile-salts. The liver is often enlarged owing to retention of bile.

Pruritus occurs in about 20 per cent. of cases, especially when the jaundice is well marked; it may be very severe and interfere with sleep. It is not directly due to the jaundice, as it may occur before the jaundice appears and continue after its disappearance; when present before the jaundice, it may subside with the onset of the latter, and it has also been observed in association with gall-stones when no jaundice was present.

The yellow vision or xanthopsia of jaundiced patients is less marked than that caused by santonin, and is rarely sufficiently obvious for the patient to mention it unless directly asked.

Diagnosis.—(a) RECOGNITION OF JAUNDICE: VAN DEN BERGH'S REACTION.—Bilirubin is normally present in the blood. Just as the kidneys in diabetes do not excrete sugar until the concentration in the blood has reached the leakage-point, which is considerably higher than the normal concentration, so no bilirubin passes into the urine until the concentration in the blood has risen from the normal of 1 in 250,000 to the leakage-point of 1 in 50,000. About the same concentration is required to cause jaundice, but the appearance of a trace of bile-pigment in the urine is easier to recognise with certainty than the first trace of pigmentation of the skin or conjunctiva. Moreover, the pigmentation is somewhat slower to develop, and it remains for a time after all pigment has disappeared from the urine.

Hijmans van den Bergh has shown that excess of bilirubin in the blood can be recognised by a colour reaction, now commonly known as van den Bergh's test, which is given by Ehrlich's diazo reagent. The *direct reaction* may be "prompt," the maximum being reached within 30 seconds; it may be "delayed" for 1 to 15 minutes or entirely negative; or it may be "biphasic," giving a slight prompt reaction, followed after a delay by gradual deepening of the colour. The *indirect reaction*, obtained after precipitation with alcohol so as to bring the bile into alcoholic solution, is always prompt.

With van den Bergh's test it is possible to distinguish two different forms of bilirubin. The direct reaction is prompt when the bilirubin is reabsorbed into the blood after it has been excreted by the hepatic cells in cases of obstructive jaundice, but is negative or delayed when the excess of bilirubin is a result of over-production, as in hæmolytic jaundice; it is negative, delayed or biphasic when the jaundice is due to inability of the hepatic cells to excrete it, as in toxic and infective hepatic jaundice.

By means of van den Bergh's test it is also possible to recognise latent jaundice. Thus the hyperbilirubinæmia present in Addison's anæmia gives a positive indirect reaction, although there is no jaundice except in occasional acute hæmolytic crises, which may result in the concentration of bilirubin in the blood being sufficient to cause the conjunctivæ and skin to

develop the yellow colour of ordinary jaundice. Excess of bilirubin in the blood at a concentration below the leakage-point may also result from a very slight degree of biliary obstruction, such as may occur with a stone in the ampulla of Vater and in some cases of cirrhosis and of secondary carcinoma of the liver; it is recognised by giving a positive direct van den Bergh's reaction in spite of the absence of jaundice and of bile from the urine. In other cases of obstructive jaundice a positive direct reaction is given at a stage before jaundice develops and bile appears in the urine, and still longer before any change is noticed in the stools.

(b) FACTORS HELPING IN THE DIFFERENTIAL DIAGNOSIS OF THE CAUSE OF JAUNDICE.

1. *Age, sex and history.*—Transient jaundice is common in the newly born (*vide* icterus neonatorum). Obstructive jaundice may result from congenital obliteration of the bile-ducts (p. 712) and congenital syphilis (p. 689). Severe jaundice in infants may be familial (*vide* familial icterus gravis neonatorum). Mild infective jaundice may occur sporadically or in epidemics among infants; it is identical with the catarrhal jaundice of older children and adults. Epidemics of very fatal jaundice were formerly common in lying-in hospitals; sporadic cases still occur. The infection may enter by the umbilicus, which is red and swollen and may bleed, or by the alimentary tract; jaundice appears about the fifth day and is accompanied by high fever and severe septic symptoms. Hæmorrhage may occur from the alimentary tract or kidneys.

Jaundice occurring in childhood or before the age of thirty is generally catarrhal; after thirty gall-stones become a more common cause, especially in women, and after forty cancer is the most common cause in both sexes. Jaundice developing in pregnancy should raise a suspicion of acute necrosis of the liver. When more than one member of a family are affected, an infection, such as spirochætal jaundice, or a toxæmia is probably the cause in acute cases; in chronic cases acholuric jaundice should be considered.

2. *Colour.*—In hæmolytic anæmia the skin has a characteristic lemon-yellow colour, though the conjunctivæ are unaffected. In toxic jaundice, such as that caused by arsenobenzene, the skin assumes a very bright yellow colour, which is quite distinct from that of ordinary jaundice caused by obstruction of the bile passages. The former is probably produced by the form of bilirubin which gives only an indirect van den Bergh reaction, and the latter is produced by the form which also gives a positive direct reaction. A dirty yellow or greenish-yellow colour occurs only in chronic and more or less complete obstructive jaundice.

3. *Course.*—Jaundice of short duration is generally catarrhal or due to the passage of a gall-stone. Jaundice, which progresses until it becomes extremely deep, suggests cancer or chronic pancreatitis, whilst chronic jaundice, which varies from time to time, and intermittent jaundice are generally due to a stone in the ampulla of Vater, but may also be due to cancer of the ampulla of Vater.

4. *Condition of the gall-bladder.*—Enlargement of the gall-bladder indicates obstruction of the cystic or common bile-duct, though the former is not likely to be associated with jaundice. The enlargement is present in over 90 per cent. of cases in which obstruction is due to causes other than gall-stones, but only in 20 per cent. of cases of calculous obstruction. This

difference is known as Courvoisier's law, and is due to the contraction of the gall-bladder as a result of chronic inflammation in cholelithiasis, in which, moreover, the obstruction is often incomplete.

5. *Condition of the liver*.—Jaundice associated with great enlargement of the liver is generally due to growth if it is irregular, and to chronic obstruction of the common bile duct if the liver is smooth; the irregular enlargement due to syphilis is less extreme, and, like that due to hydatid cysts or an abscess, is rarely associated with jaundice. The presence of ascites points to a growth or to cirrhosis, but the jaundice is generally more marked in the former.

6. *Examination of the stools*.—The presence or absence of stercobilin in the stools shows whether the common bile-duct is incompletely or completely obstructed, and the presence or absence of trypsin shows whether the pancreatic ducts are free or obstructed. Slight excess of fatty acid and soap without any striated meat fibres or starch occurs in uncomplicated jaundice; excess of neutral fat, as well as fatty acid and soap, together with striated meat fibres, but not starch, points to obstruction of the pancreatic duct. Complete absence of both bile and pancreatic juice from the intestinal contents indicates obstruction of the common bile-duct by a growth. Incomplete obstruction of the bile-ducts without interference in pancreatic digestion points to gall-stones, catarrhal jaundice or chronic pancreatitis.

7. *Pain*.—Constant pain suggests growth, attacks of pain gall-stones, and absence of pain catarrhal jaundice, chronic pancreatitis or cirrhosis; but many exceptions to this general statement occur.

8. *Syphilis*.—Active signs of syphilis or scars of old lesions should raise the possibility of a syphilitic origin, or of poisoning by an organic arsenical preparation which a patient may be having for syphilis without his own doctor's knowledge.

Treatment.—The treatment of jaundice is the treatment of the condition which causes it. The subject, therefore, requires no further consideration here, except for the pruritus and tendency to hæmorrhage, which are results of the jaundice itself. Dried thyroid, $\frac{1}{2}$ gr. three times a day, may give relief to the pruritus, which is also helped by a warm alkaline bath, or moistening the irritable parts of the skin with 1 in 40 carbolic acid, 1 in 50 ichthyol, or 1 in 70 solution of menthol in spirit. The tendency to hæmorrhage is much reduced by the subcutaneous injection of calcium salts, and it is advisable to treat every jaundiced patient in this way for a few days before any operation is performed.

SIMPLE JAUNDICE IN INFANTS (ICTERUS NEONATORUM)

Ætiology.—Simple jaundice occurs in about 50 per cent. of infants, and especially among the premature.

Pathology.—The number of red corpuscles is high in the newly born, but quickly falls during the first few days of life. The excessive blood destruction is associated with an excess of bile-pigment in the blood, as shown by van den Bergh's reaction, which gives a positive indirect but negative direct reaction in all new-born infants. The jaundice is therefore hæmolytic, and when death occurs from some independent cause nothing abnormal is found in the liver or bile-ducts.

Symptoms.—The jaundice generally begins on the second or third day of life; it increases in intensity for 2 or 3 days and then gradually diminishes until it disappears after 1 or 2 weeks, but occasionally it lasts for a longer period. The jaundice begins on the face and spreads over the whole of the body; unlike other forms of jaundice, the conjunctivæ are affected after the skin, and in mild cases they are not stained at all.

Diagnosis.—If the jaundice is slight, its presence can only be recognised by pressing the blood out of the cutaneous vessels, when the normal redness of the infant disappears and the yellow colour remains. Its short duration and the absence of enlargement of the liver and spleen distinguish simple icterus neonatorum from congenital obliteration of the bile-ducts, and the healthy condition of the infant distinguishes it from the infective forms of jaundice.

Prognosis and Treatment.—Rapid recovery always occurs, and no treatment is required.

FAMILIAL ICTERUS GRAVIS NEONATORUM

The jaundice, which affects successive members of the same family, though the first-born often escapes, begins within a few hours of birth. The colour rapidly deepens till the skin is deep bronze. The infants are drooping and take the breast badly. The stools are normal in colour. The urine is dark and contains urobilin and often bilirubin in excess. The liver and spleen are not enlarged.

The quantity of bilirubin in the blood at birth is greater than normal; the blood contains no hæmolyisin, but the cells show a slight increased tendency to hæmolysis (Hampson).

Death generally occurs within a few days and almost always within 3 weeks: post mortem nothing abnormal is found. Hampson has shown that complete recovery occurs if 15 c.c. of the mother's blood serum are injected daily for 3 or 4 days into the infant's muscles.

ACHOLURIC JAUNDICE

Synonym.—Chronic Splenomegalic Hæmolytic Jaundice.

Ætiology.—The disease may be hereditary and familial, when it is either congenital or only appears some years after birth, the two varieties sometimes co-existing in the same family. The disease may occur in as many as four generations and may be transmitted through healthy parents. It may also be acquired in adult life without obvious cause or after some infection.

Pathology.—The red corpuscles, which are smaller than normal and biconvex instead of biconcave, are abnormally "fragile," undergoing hæmolysis with remarkable ease. This fragility leads to the liberation of hæmoglobin and the formation of excess of bilirubin in the blood. No hæmolytic toxin is present in the blood, the hæmolysis being apparently due to the fragility of the corpuscles resulting from inheritance or an infection.

There is no evidence that the jaundice is obstructive, as the bile-ducts are free from inflammation and evidence of obstruction, and the bile is not

abnormally thick. It appears, therefore, that the jaundice is hæmatogenous and due to the formation of bilirubin from hæmoglobin in the tissues.

Symptoms.—(a) **FAMILIAL TYPE.**—The jaundice may vary in degree from time to time, and may temporarily almost disappear; it is increased by excitement, over-exertion and exposure to cold. No symptoms of chronic jaundice, such as pruritus, xanthoma and a slow pulse, are present. The urine is free from bile, but is dark and generally contains urobilin, and the fæces are normal in colour. In the exacerbations, however, bile may appear temporarily in the urine and the fæces become pale.

In some cases attacks of colic, which may be accompanied by pyrexia and aggravation of the jaundice occur; they are caused by pigment calculi, which are generally found in the gall-bladder in cases requiring operation, though in most cases they do not give rise to symptoms. Except for these attacks the general health is hardly affected.

The red blood corpuscles are abnormally fragile; they begin to undergo hæmolysis in a 0·6 per cent. sodium chloride solution and the process is complete in a 0·42 per cent. solution, whereas hæmolysis in normal blood begins in a 0·42 per cent. sodium chloride solution and is complete in 0·3 per cent. solution. The corpuscles are smaller than normal, but as they are also thicker their total volume is not reduced. Stained films show well-marked polychromatophilia and basophil granules. Moderate anæmia is generally present, and the colour-index is less than one. The blood plasma contains excess of bilirubin, but no free hæmoglobin. The spleen is enlarged, but the liver is unaffected.

(b) **Acquired type.**—In the acquired form of the disease the jaundice is less marked, but the anæmia is more severe; it may resemble that of Addison's anæmia with a high colour-index and nucleated corpuscles. Leucocytosis is present, and myelocytes with excess of eosinophil cells are found. The fragility of the corpuscles is less marked than in the congenital form. Attacks of febrile colic occur, and symptoms of anæmia are present.

Diagnosis.—The diagnosis depends upon the characteristic fragility of the red blood corpuscles. In the acquired form, in which the fragility is less marked, Addison's anæmia with jaundice may be closely simulated; but in the latter condition the resistance of the corpuscles to hæmolysis is actually greater than normal and leucopenia due to diminution in the number of polymorphonuclear cells is present. The febrile and painful attacks are indistinguishable from ordinary biliary colic, and are, indeed, commonly due to gall-stones; but the history and the condition of the blood should prevent a mistake in diagnosis. An examination of the blood also helps to distinguish those cases in which jaundice is slight from splenic anæmia.

Prognosis.—The symptoms in the hereditary and familial forms of the disease have no tendency to disappear; but the condition does not interfere with normal growth or shorten life, and the patient cannot really be considered ill. On the other hand, in the acquired form, although the symptoms are much more serious, spontaneous recovery is possible.

Treatment.—The patient should avoid everything, such as exposure to cold and over-exertion, which is likely to lead to exacerbations. In severe cases splenectomy should be performed, as it is followed by rapid disappearance of the jaundice and anæmia, and in most cases the fragility

of the red corpuscles returns to normal. Attacks of biliary colic may call for cholecystectomy and removal of stones from the common bile-duct; unless splenectomy is performed at the same time, the attacks are likely to recur owing to the formation of more stones in the bile-ducts.

CATARRHAL JAUNDICE

Ætiology and Pathology.—Catarrhal jaundice is a condition in which jaundice results from obstruction of the mouth of the common bile-duct by the swollen mucous membrane and thick mucus caused by catarrh of the biliary papilla. This is generally a sequel of gastro-duodenal catarrh, the inflammation spreading through the biliary papilla for a short distance up the common bile-duct. The primary gastro-duodenal catarrh most commonly develops without obvious cause; but it may follow food-poisoning and also occur as a symptom of an acute infection, such as influenza, pneumonia and very rarely typhoid and paratyphoid fevers. The epidemic jaundice which occurred during the Gallipoli campaign in 1915 was indistinguishable from ordinary catarrhal jaundice and was quite distinct from spirochætal jaundice. In some cases the cholangitis spreads to the smallest bile-ducts and may then be associated with hepatitis, the jaundice being partly hepatic and partly obstructive. Thus, whereas the van den Bergh test sometimes gives a prompt direct action, in other cases, clinically indistinguishable, it gives a biphasic or delayed direct action. In the former cases, which are in my experience the more common, the lævulose test shows no impairment in hepatic efficiency except in the late stages of unusually chronic cases; in the latter it shows more or less impairment. In exceptional cases the hepatitis may proceed to fatal necrosis.

Attacks of jaundice caused by non-specific infective hepatitis without clinical or post-mortem evidence of gastro-duodenitis have been classified as catarrhal jaundice, but the pathology of this condition is quite distinct from that under consideration and the term infective hepatitis should be used for it.

Symptoms.—Jaundice is almost invariably preceded for one, two or three days by symptoms of acute gastritis. The patient complains of epigastric discomfort, most marked immediately after meals, with nausea and often vomiting, which relieves the discomfort. The appetite is lost, headache and general malaise are present, and there may be diarrhœa. Slight pyrexia is common. The stools become pale and the urine contains bile before jaundice is obvious. As the jaundice develops, the gastric and general symptoms abate. The patient becomes deeply yellow, but is by now often quite comfortable so long as he keeps quiet, though activity tends to bring on vomiting. The liver is generally enlarged, and the gall-bladder may be palpable. The liver is slightly tender, but there is no increased tenderness over the gall-bladder. The spleen may also be enlarged.

In slight cases the jaundice begins to disappear in a week, but it may persist for a month or even for as long as three or four months. The stools become more coloured before the jaundice is obviously less; the quantity of bile in the urine then gradually diminishes, but three or four more weeks may elapse before the last trace of jaundice and the last trace of bile in the

urine disappear. In epidemics mild cases occur in which no jaundice follows the initial symptoms caused by the acute gastro-duodenitis.

Diagnosis.—When jaundice, unaccompanied by pain and with very slight constitutional symptoms, develops in a patient with mild gastric symptoms of a few days' duration, catarrhal jaundice is the probable diagnosis. When the symptoms do not abate with the onset of jaundice and much constitutional disturbance is present, especially if the spleen is enlarged and herpes or purpura occurs, the possibility of spirochaetosis, ictero-hæmorrhagica requires consideration. When the initial gastric symptoms are absent and the jaundice persists for more than six weeks, especially in elderly patients, or when the colour changes from yellow to green, the possibility of chronic pancreatitis or of a growth must be considered. When pain of any severity occurs, especially after the onset of jaundice, and when the gall-bladder is tender, fever persists or the jaundice recurs, gall-stones are probably present.

Treatment.—The patient should be kept in bed on a plain diet containing as little fat as possible. The bowels should be opened daily with Epsom salts, which at the same time promote biliary drainage. The patient should not be allowed to get up until the jaundice is beginning to disappear.

CONGESTION OF THE LIVER

Ætiology.—When the outflow of blood from the hepatic vein is impeded as a result of right-sided heart failure, due to primary disease of the heart or to obstructive pulmonary disease, passive congestion of the liver may result. It is also produced by thrombosis of the hepatic veins, which is a rare condition generally secondary to some neighbouring malignant, syphilitic or inflammatory disease.

Pathology.—The sublobular and intralobular veins are dilated. The centre of each lobule thus appears as a dark spot, whilst the outer part is pale owing to fatty infiltration; the mottled appearance resembles the section of a nutmeg and has led to the name "nutmeg liver."

Symptoms.—In addition to the symptoms of the cardiac or pulmonary disease, which has led to the right-sided heart failure, special symptoms result from the passive congestion of the liver. The capsule of the liver is stretched and pain results, especially if the enlargement is rapid. When the increase in size is more gradual there is a feeling of fullness and weight in the right hypochondrium. The liver can be felt to extend considerably lower than normal, its size varying from time to time according to the condition of the heart. It is firm and tender, especially if the congestion is recent and acute. Distinct expansile pulsation can sometimes be felt by placing one hand in the loin and the other just below the right costal margin; this corresponds with ventricular systole if tricuspid regurgitation exists and with auricular systole if there is tricuspid stenosis. It must be distinguished from the non-expansile pulsation transmitted through the diaphragm from the hypertrophied and labouring right ventricle.

The congestion of the liver leads in turn to congestion of the organs which are drained by the portal vein. Anorexia, discomfort immediately after food, flatulent distension of both stomach and intestines from deficient

absorption of the gas swallowed with the food or produced by fermentation, and constipation are commonly present. The combination of slight jaundice with cyanosis produces a characteristic dusky green colour of the face.

Ascites is common, but is rare in the absence of general œdema, being mainly due to the same causes; it is also in part a direct result of portal congestion and sometimes of chronic peritonitis. The spleen is very rarely enlarged in spite of the interference with the outflow of blood in the splenic vein by the hepatic congestion.

Diagnosis.—When the heart disease is obvious, the diagnosis is easy. Sometimes, however, the most prominent symptoms are due to the congestion of the liver, and the diagnosis from cirrhosis may be difficult. In congestion of the liver the spleen is not enlarged, and the symptoms rapidly improve and the liver diminishes in size with rest and cardiac tonics; moreover, hæmatemesis, though common in cirrhosis, very rarely occurs in passive congestion in spite of the congestion of the gastric mucous membrane.

A history of alcoholism does not necessarily point to cirrhosis: if the heart is failing and there is no valvular disease, the enlargement of the liver is probably due to congestion and the heart failure to alcoholic poisoning. The diagnosis would be confirmed if the ankle-jerks are lost, as latent alcoholic neuritis is frequently associated with an alcoholic heart and a cardiac liver, but rarely with cirrhosis.

Treatment.—Apart from the treatment of the primary condition the local pain and discomfort are rapidly relieved by the application of six leeches over the hepatic region. Mild purgation with Epsom salts also helps to relieve the portal congestion.

INFLAMMATION OF THE LIVER (HEPATITIS) AND DEGENERATION OF THE LIVER (HEPATOSIS)

From analogy with the corresponding conditions in the kidneys, inflammation of the liver should be called hepatitis and degeneration of the liver hepatosis. But as it is impossible to draw a definite line between inflammation and degeneration even after death, this classification is difficult to carry out in practice. It would, however, be preferable to the exceedingly confusing nomenclature in use at present. Thus "acute yellow atrophy" is really acute necrosis caused by acute hepatosis and "cirrhosis of the liver" is chronic hepatitis. The "icterus gravis" of acute infections and poisoning by various organic toxins and chemical substances is really one form of acute necrosis of the liver; as jaundice may be slight or absent in very acute cases of the latter, icterus gravis is not a very appropriate name. The pre-cirrhotic stage of chronic alcoholic poisoning of the liver is a chronic hepatitis, but is generally known as "active congestion of the liver," under which heading it was described in the last edition of this book. As the distinction between nephritis and nephrosis is largely artificial, and many authorities would prefer to retain the old name of nephritis to include both, I think it would be best at present to call all of these conditions hepatitis

rather than to introduce a new word, *hepatosis*. The classification of the various diseases under consideration would then be as follows :

A. TOXIC HEPATITIS.

- (a) Alcohol : (1) acute (a form of acute necrosis) ;
 (2) chronic : i. pre-cirrhotic alcoholic hepatitis ;
 ii. cirrhosis of the liver (Laennec's cirrhosis).
- b) Delayed chloroform poisoning ; poisoning with chloral, and with carbon tetrachloride used in treatment of ancylostomiasis.
- (c) Arsenic : (1) acute in arseniuretted hydrogen poisoning ;
 (2) subacute in poisoning with arsenolbenzene preparations used in the treatment of syphilis.
- (d) Phosphorus poisoning.
- (e) Trinitrotoluene and tetrachlorethane poisoning, which caused the epidemic of jaundice in munition and aeroplane workers respectively during the Great War (p. 407).
- (f) Poisoning with quinophen (also known as atophan and cin-cophen).
- (g) Poisoning with santonin, filix mas, acetanilide, aniline.
- (h) Snake poisoning.
- (i) Mushroom poisoning.
- (j) Toxic jaundice of pregnancy, generally indistinguishable from acute hepatic necrosis.
- (k) Acute hepatic necrosis of unknown causation.
- (l) Banti's disease, in which a poison produced in the spleen gives rise to a condition indistinguishable from alcoholic cirrhosis of the liver.
- (m) The toxin which causes chronic lenticular degeneration associated with cirrhosis of the liver (Wilson's disease). A similar association of lenticular degeneration with hepatitis may occur in chronic manganese poisoning.
- (n) The toxin which causes hæmochromatosis.

B. INFECTIVE HEPATITIS.

The infection may be systemic and conveyed by the hepatic artery ; it may come from the alimentary tract and be conveyed by the portal vein, which supplies the liver with three-quarters of its blood ; it may reach it by lymphatics, though this must be of comparatively small importance ; and it may ascend the bile-ducts from the duodenum.

(a) *Systemic blood infections*.—Hepatitis is always a part of the clinical picture in yellow fever, spirochætosis ictero-hæmorrhagica and the jaundice of secondary syphilis. Less frequently it occurs in malaria and typhoid fever and very rarely in influenza. A non-specific infective hepatitis may simulate catarrhal jaundice.

(b) *Portal infections*.—Acute, subacute and chronic amœbic hepatitis and suppurative pyelephlebitis are the most obvious forms of infection carried by the portal vein. A mild degree of hepatitis, generally insufficiently severe to cause symptoms or to give a positive lævulose test or van den Bergh

reaction and only recognisable on microscopic examination, may occur in any chronic infection in the portal area, but it is of no clinical importance.

(c) *Lymphatic infection*.—The chronic hepatitis with fibrosis constantly found in the neighbourhood of a diseased gall-bladder is the result of chronic capillary lymphangitis in the capsule and in and around the walls of the intrahepatic bile-ducts, which has spread from the gall-bladder by its lymphatics. It is the cause of the tenderness of the liver often found in the neighbourhood of the gall-bladder in cases of cholecystitis.

(d) *Hepatitis secondary to ascending cholangitis*.—This results from infection occurring with a stone in the common bile-duct or ampulla of Vater, a stricture of the common bile-duct following an injury at operation, and obstruction of the common bile-duct by a growth. In rare cases it develops as an independent disease, probably as a result of ascending infection from the duodenum. In these conditions cellular infiltration and new fibrous tissue form round the bile ducts owing to ascending infection of the stagnant bile and ascending lymphangitis around the ducts. "Biliary cirrhosis" finally results, this being one of the conditions which was formerly included under the name of Hanot's cirrhosis.

ACUTE AND SUBACUTE NECROSIS OF THE LIVER

Synonym.—This condition was formerly known as acute and subacute yellow atrophy of the liver, but the term "necrosis" is preferable, as the pathological change is necrosis rather than atrophy, and the liver may be red rather than yellow in the less acute cases.

Definition.—Acute and subacute necrosis of the liver are rare and very fatal diseases, in which jaundice, diminution in the size of the liver, fever and nervous symptoms are caused by necrosis of the liver cells.

Ætiology.—Most cases occur between the ages of 20 and 30. Adult females are affected twice as often as adult males owing to the fact that pregnancy is one of the chief exciting causes, but the proportion is reversed in childhood. The disease may result from most of the causes of acute toxic and infective hepatitis described above, including alcohol, chloroform, phosphorus, atophan, secondary syphilis, typhoid fever and influenza. In many cases, however, no cause is discovered.

Pathology.—The condition is caused by a very acute necrosis of the liver cells, the intracellular ferments of which are set free and produce autolysis. If death occurs within 2 or 3 days the liver is enlarged and yellow owing to distension of the hepatic cells with fat globules. These cells are rapidly absorbed, so that if death occurs after a week or more the liver shrinks to only half or a third of the normal weight. Its surface is smooth and the capsule loose and wrinkled. Externally it is greenish-yellow or normal in colour, and on section bright yellow with red areas, which represent a late stage of the yellow necrosis, the fat and necrotic tissue having been absorbed, so that the vascular fibrous tissue is alone left. In subacute cases nodular hyperplasia of the surviving hepatic tissue occurs.

Symptoms.—In the first stage jaundice is present with fever, malaise, vomiting, constipation and muscular pains, the condition closely resembling catarrhal jaundice. In about a third of the cases the patient suffers from

general malaise for some time before the jaundice appears, and in rare instances jaundice is absent throughout. This first stage generally lasts for 5 or 6 days, but it occasionally persists for several weeks.

The second stage, that of hepatic failure, begins suddenly with drowsiness, headache, photophobia, restlessness and delirium with characteristic maniacal shrieking and wailing. Muscular twitching and occasionally general convulsions follow, and the patient may become violent. Transient squint is sometimes present, the pupils are generally dilated, and there is often an extensor plantar reflex. Retraction of the head may be present, and a lumbar puncture may be required to diagnose the condition from meningitis. Severe vomiting occurs, and the vomiting material may contain altered blood. The tongue is dry and tremulous. The pulse becomes rapid and feeble, but the temperature is generally subnormal, though it often rises just before death. An erythematous rash is sometimes present. Purpura is common, and hæmorrhage may also occur from the gums, nose, kidneys, uterus and alimentary canal, and in the retina. Coma finally develops with Cheyne-Stokes respiration and incontinence of urine and fæces, the whole of the second stage lasting less than a week and often only 3 or 4 days.

The liver is often enlarged and tender in the first stage, but at the onset of severe symptoms it rapidly diminishes in size, until the hepatic dullness disappears owing to the atrophied and flabby liver falling back and allowing the intestines to pass between it and the abdominal wall. The spleen is sometimes enlarged. Ascites is rarely detected during life, though it may be found after death.

There is no anæmia, but moderate leucocytosis.

The urine contains bile and albumin, and casts are often present. There is no glycosuria. The percentage of nitrogen excreted as ammonia increases from the normal of about 5 to 20 owing to the acidosis, which causes ammonia to be fixed by organic acids before there is time for it to be converted into urea. Rounded discs of leucin and needle-shaped crystals of tyrosin derived from autolysis of the liver cells may be deposited in the urine when it cools, but they are sometimes only found after concentration and may be absent altogether, though they are subsequently discovered in the liver. They are also occasionally found in the urine in typhoid fever, erysipelas, small-pox and leukæmia, so that their presence is not pathognomonic of acute necrosis of the liver.

Diagnosis.—The diagnosis depends upon the occurrence of severe general symptoms and diminution in the liver dullness in association with jaundice. In phosphorus poisoning the diagnosis may be obvious from the history; the symptoms differ from those of other forms of acute necrosis in the absence of progressive diminution in the hepatic dullness, in the comparative mildness of the cerebral symptoms, and in the interval which elapses between the severe gastric symptoms and the onset of jaundice.

It is sometimes impossible to distinguish between subacute necrosis and subacute cirrhosis, as clinically and pathologically they merge into each other.

Prognosis.—More than half the cases are fatal within a fortnight, but the first stage of the disease may be prolonged over many weeks or months and even as long as 2 years. Prolonged and subacute cases occur most frequently in children; they are difficult to differentiate from subacute

cirrhosis with jaundice. As nodular hyperplasia of the liver has been found in cases surviving 6 months, 1½ years and 2 years, there is a possibility of permanent recovery, but it is probable that most of the recorded cases of recovery were really examples of spirochætal jaundice. As children more often show the changes of subacute atrophy, the prognosis is rather less hopeless in them than in adults.

Treatment.—When jaundice occurs in pregnancy or in secondary syphilis, or when a patient with supposed catarrhal jaundice becomes drowsy or shows other toxic symptoms, the possibility of acute necrosis developing should be remembered, as treatment is much more likely to be successful if begun at this stage than when the second stage has fully developed. The diet should consist of milk and carbohydrate food only, and large quantities of fluid should be drunk; if there is much vomiting, saline solution should be given by the rectum and subcutaneously. Large quantities of sodium bicarbonate may be required to counteract the acid intoxication. Intravenous injection of 10 to 20 per cent. dextrose solution, with small doses of insulin, with the object of “fixing” the glycogen in the liver, has recently been tried with success. In infective cases an attempt should be made to disinfect the bile passages with hexamine (p. 705).

AMŒBIC HEPATITIS AND HEPATIC ABSCESS

Ætiology.—Amœbic hepatitis is very rare before the age of 20 and is most common in the third and fourth decades. Amœbic hepatitis and amœbic abscess of the liver are invariably secondary to amœbic dysentery. In 98 per cent. of fatal cases Rogers either obtained a history of dysentery or found amœbic ulcers or scars of ulcers in the large intestine. The patient had had dysentery in the past or was still suffering from it in about 75 per cent. of acute and subacute cases, and in an additional 15 per cent. there was a history of diarrhœa, which was doubtless a mild form of amœbic dysentery; in the remaining cases amœbic ulcers had probably been present in the cæcum or ascending colon, situations in which they do not necessarily give rise to any symptoms. Dysentery may precede the development of an abscess by months or even years—in one of my cases by 16 years. When hepatitis develops during an attack of dysentery, the latter generally becomes less severe as the inflammation in the liver progresses.

The geographical distribution of the disease is identical with that of amœbic dysentery, but as it may develop in chronic cases and long after the onset of dysentery, it is not uncommon, especially in the chronic form, among individuals who have returned to Europe from the tropics. Chronic alcoholism is an important predisposing cause.

Pathology.—The amœbæ, which collect in the thrombosed veins at the base of dysenteric ulcers, pass to the liver by the portal vein. Nothing more is known as to the pathology of non-suppurative amœbic hepatitis, as death does not occur unless an abscess forms, but the hepatic insufficiency, which is always found by the lævulose test to be present, indicates that the infection is widespread and uniform through the liver. An abscess forms if a local accumulation of amœbæ gives rise to thrombosis in a portal radicle. The circulation is obstructed and necrosis of the surrounding tissue occurs;

at the same time pus is secreted as a result of the irritant action of the amœbæ on the liver tissue. The wall of the abscess is at first formed by necrotic liver tissue, but the cavity gradually becomes limited by a fibrous capsule produced by the inflammatory reaction. In 70 per cent. of cases a single abscess is present; in nearly half of the others there are 2 abscesses, in a quarter there are 3, and in the remainder there are 4 or more. A single abscess is found five times as often in the right as in the left lobe of the liver.

The pus generally contains amœbæ but no bacteria; in chronic cases all the amœbæ may have died, but they can still be found in the material obtained by scraping the wall of the abscess. In rare cases an amœbic abscess becomes spontaneously sterile, and its dried remains have been found at a post-mortem examination years afterwards. When an hepatic abscess reaches the surface, adhesions form between the liver and the adjoining structures, so that the contents of the abscess may burst into the lung, stomach or bowel, or open externally without infecting the serous cavities.

ACUTE AND SUBACUTE AMŒBIC HEPATITIS AND HEPATIC ABSCESS

Symptoms.—About one-tenth of the cases of acute amœbic hepatitis occurring in India are of a fulminating type, in which the whole liver is riddled with small collections of pus with no fibrous tissue separating them from the surrounding liver substance—a condition which rarely, if ever, occurs outside the endemic areas. There is always a definite history of dysentery, which is often still present when the hepatitis develops. The liver rapidly increases in size; it is very painful and extremely tender. Slight jaundice may be present. The temperature is high with rapid remissions, the rise being often accompanied by rigors and the fall by copious sweating. Leucocytosis is well marked. Death generally occurs between 6 and 18 days from the onset of symptoms.

As most cases of subacute amœbic hepatitis subside completely with injections of emetine, it is clear that in the early stages no suppuration is present. Discomfort and a sense of weight are felt in the right hypochondrium in the slighter cases, but in the more severe ones the pain may be so great that the patient is hardly able to move, and he is often unable to lie on his left side owing to the dragging pain caused by the change of position. Pain may also be referred to the right shoulder and occasionally to the right arm, especially when the upper part of the liver is involved. The liver is enlarged and tender, but the rigidity of the abdominal muscles may be so great that it is impossible to feel its edge. Pressure exerted on the lower part of the right thorax, with one hand behind and the other in front, gives rise to pain. Slight jaundice is occasionally present in the severer cases. The appetite is impaired or lost, and the patient rapidly becomes weak and emaciated.

The temperature is generally remittent, varying between 100° in the morning and 103° or 104° in the evening. In severe cases it remains high with only small remissions, but in more chronic cases, especially when the abscess bulges through the capsule of the liver and the tension within its cavity consequently falls, the fever is less marked; it may then be low, continued or relapsing, and may finally disappear. Copious sweating is

common in the more severe cases. Moderate leucocytosis is always present, and the proportion of polymorphonuclear cells is considerably increased, especially when actual suppuration has occurred; if the percentage is less than 70, simple hepatitis, and not an abscess, is probably present.

The upper part of the liver is most frequently involved, and the main increase in dullness is then in the upward direction, but the lower border is also abnormally low. The lower ribs bulge, and the intercostal spaces become wider; the edges of the ribs become less clearly defined, and the skin may be definitely œdematous even in acute hepatitis without suppuration. At an early stage the breath-sounds become feeble and the percussion note impaired at the right base; the X-Rays show that the right side of the diaphragm is abnormally high, and when suppuration occurs its movements are diminished and finally cease completely. If the diaphragm is perforated by an abscess of the liver, a pulmonary abscess, or less frequently an empyema, develops. In the former case large quantities of thick reddish pus are expectorated, and, if emetine is given, rapid recovery generally results.

An abscess in the anterior and lower part of the right lobe produces a tender tumour in the right side of the epigastrium, the lower ribs become prominent, and the lower border of the liver can either be felt or is found by percussion to be displaced downwards. A rub may be heard when an abscess reaches the surface of the liver, but it disappears on the formation of adhesions with the anterior abdominal wall. In advanced cases the skin becomes œdematous, fluctuation is present, and the abscess may open externally just below the costal margin. Less frequently the abscess reaches the under surface of the liver, when it may rupture into the duodenum or hepatic flexure; pus is then passed per rectum, and the tumour suddenly diminishes in size. The general condition of the patient immediately improves, the temperature falls, and spontaneous recovery may follow.

An abscess in the left lobe of the liver generally gives rise to a tender tumour in the epigastrium. An abscess bulging from the lower or upper surface of the left lobe is less easily diagnosed; it may escape recognition till it ruptures respectively into the stomach, when the characteristic thick reddish pus is vomited, or into the left lung or pericardium.

In some cases the X-Rays show a localised increased density in the hepatic shadow, especially if the abscess is in the left lobe or if it is large and surrounded by a thick fibrous capsule. Localised subdiaphragmatic, subhepatic and retroperitoneal abscesses are uncommon complications, and general peritonitis rarely develops.

Diagnosis.—The possibility of amœbic hepatitis or hepatic abscess should be considered whenever an individual, who has been in the East, is suffering from progressive deterioration in health with more or less pyrexia, especially if the latter is remittent and accompanied by chills and sweats, and if obscure abdominal symptoms are present.

Subacute hepatitis is most commonly confused with malaria; but the rise of temperature in hepatitis is generally in the evening instead of during the day, and the liver is enlarged out of proportion to the spleen instead of *vice versa*, leucocytosis is present with a relative increase of polymorphonuclear cells and only 2 to 4 per cent. large mononuclear cells, in contrast with the normal or subnormal count with 15 to 20 per cent. large mononuclear cells found in malaria; the malarial parasite cannot be found in

the blood, and emetine gives good results, whilst quinine fails to influence the pyrexia.

A localised tumour in the liver in a man who has been exposed to amœbic infection is generally an abscess and more probably amœbic than a suppurating hydatid cyst; it is elastic or fluctuating unlike the hard solid tumour formed by a gumma and a growth.

Prognosis.—Until 1907 hepatic abscess was the second commonest cause of death in the British Army in India, but the incidence of the disease has become much smaller since amœbic dysentery has been treated by emetine injections, and the mortality has been greatly reduced since the necessity for operation has become comparatively rare owing to the frequency with which treatment is instituted in the pre-suppurative stage. The prognosis is best if the abscess is single, as multiple abscesses are difficult to locate, and their evacuation may be impossible, especially in the rare fulminating cases.

Treatment.—In acute hepatitis without suppuration very rapid improvement follows the subcutaneous injection of 1 grain emetine hydrochloride on 12 or more consecutive days; the hepatic tenderness diminishes within 8 hours of the first injection, and the temperature may fall to normal in 24 hours. As there are no definite signs which distinguish acute hepatitis without suppuration from hepatic abscess unless a definite tumour is present, no local treatment should be adopted until emetine injections have been given daily for a week without producing any improvement. Even a small abscess may be completely absorbed without aspiration after the amœbæ in its walls have been killed by subcutaneous injections of emetine.

The most satisfactory treatment of an abscess is evacuation by aspiration, emetine being injected subcutaneously in order to kill the amœbæ in the abscess wall and in any ulcers which are still present in the colon. If the pus reaccumulates, a grain of emetine hydrochloride dissolved in an ounce of water should be injected into the abscess cavity after it has been aspirated. The results with this treatment are so successful that the open operation, which is frequently followed by prolonged convalescence or death owing to secondary infection, is now only required in the comparatively rare cases, in which the situation of the abscess cannot be determined, or bacteriological examination of the pus obtained by aspiration shows that the abscess already contains pyogenic bacteria. When an abscess has been opened or has ruptured into the lung, stomach or bowel, subcutaneous emetine injections should be continued until the temperature has remained normal for a week.

CHRONIC AMŒBIC HEPATITIS

Amœbic dysentery is almost always associated with hepatic insufficiency, as demonstrated by the lævulose test, although in a large majority of cases there is no sign of hepatic disorder. As acute and subacute hepatitis and hepatic abscess are common complications of amœbic dysentery, it seems reasonable to assume that the functional deficiency of the liver in these cases is caused by a mild and latent form of amœbic hepatitis.

It is not uncommon to find hepatic insufficiency in patients complaining of unfitness since returning from a country in which amœbic dysentery is endemic. Some have had definite dysentery, but others have had nothing

more than a few attacks of diarrhoea, and occasionally they have never had intestinal symptoms of any kind.

Symptoms.—The patient complains of general unfitness and is easily fatigued. Very often he rightly describes himself as liverish. He generally suffers from a constant ache over the liver. His appetite is poor, and he is pale and sallow, though generally not anæmic, and true jaundice is never present. There is no pyrexia, and the leucocyte count is normal. The whole of the exposed surface of the liver is tender, and the lower border is often more easily palpable than normal, but there is very little enlargement. Amœbic cysts are very rarely found in the stools, but in a small proportion of cases, in spite of the absence of intestinal symptoms, the sigmoidoscope has revealed the presence of small but typical amœbic ulcers—raised red spots with a necrotic centre on a normal pink mucous membrane, very closely resembling boils on the skin. Not infrequently the cæcum and ascending colon are tender, and the stools may contain traces of occult blood, presumably the result of chronic amœbic typhlitis.

Diagnosis and Treatment.—The diagnosis is quickly confirmed by the result of treatment. The injection of 1 grain of emetine hydrochloride every night for twelve nights results in the disappearance of all symptoms, and the lævulose test shows that there is no longer any hepatic insufficiency. In one case, for example, the rise in the blood sugar was 55 mgrm. per 100 c.c. one hour after taking 50 gm. of lævulose and in two hours it had only fallen 25 mgrm.; after treatment the one-hour rise was 6 mgrm. per 100 c.c., and in two hours the blood sugar was the same as before the lævulose had been taken.

It is necessary, however, to give further courses of six or more injections 3, 6 and 12 months later in order to prevent recurrence. This treatment is more efficacious and far less upsetting to the patient than the administration of the various other drugs which have been recommended for the treatment of amœbiasis.

PRE-CIRRHOTIC ALCOHOLIC HEPATITIS

Definition.—In the early stages of chronic alcoholic poisoning of the liver complete or almost complete recovery may take place if the patient becomes teetotal. Not only do the symptoms disappear, but the liver becomes smaller and softer, and the lævulose test, which originally showed gross hepatic insufficiency, shows little or no abnormality. Though there is no pathological evidence as to the exact condition of the liver before and after treatment, it is clear that actual cirrhosis cannot have taken place. It is therefore reasonable to regard the condition as pre-cirrhotic and to call it alcoholic hepatitis or hepatosis.

Ætiology.—Whereas the fully developed picture of cirrhosis of the liver has become rare since the war, alcoholic hepatitis has become increasingly common, especially among the well-to-do. Whilst the poor man's beer is more expensive and weaker than it was before 1914, many people celebrate their newly acquired wealth by excessive indulgence in cocktails, champagne and whisky. Some have been drinking in obvious excess, though they may never get drunk, but with others it is the kind of

alcohol and the time at which it is consumed rather than the total quantity which are mainly responsible for the damage done to the liver. Consequently alcoholic hepatitis is not at all uncommon among young adults of both sexes, though fully developed cirrhosis is now, as it has always been, rare before middle age. In older patients a sedentary life is an important predisposing factor.

The condition has long been recognised as common among Europeans living in tropical countries, where the consumption of highly spiced food and repeated attacks of malaria, together sometimes with amœbiasis and enteric fever, are additional factors.

Symptoms.—A feeling of discomfort, rarely amounting to actual pain, is felt in the region of the liver. Symptoms of alcoholic gastritis, especially morning anorexia and nausea, are often present with hypochlorhydria or achlorhydria and excess of mucus in every fraction of a test-meal. The patient's complexion is sallow, and there is sometimes a slight degree of jaundice. The liver is hard, moderately enlarged and tender, and the spleen may be just palpable. The patient says he is "liverish"; he is irritable and depressed, and complains of a feeling of general unfitness, headache and drowsiness.

Periods of comparative well-being may alternate with acute exacerbations or "liver attacks," which are generally caused by increased alcoholic excess and to a less extent by over-eating, and sometimes by exposure to cold. During such an attack the liver becomes larger and more tender, and the stretching of the capsule may cause acute pain. In rare cases hæmatemesis occurs. With suitable treatment an attack generally subsides within a fortnight, and even in severe cases a month or six weeks is generally sufficient to restore the patient to good health. If he becomes teetotal complete recovery may occur; otherwise definite cirrhosis will eventually develop.

Ascites never occurs in the pre-cirrhotic stage.

Treatment.—The patient should be kept in bed on a diet of citrated milk until all the symptoms have disappeared and the liver is no longer tender; if gastritis is present, the stomach should be washed out every morning (p. 578). The diet can then be gradually increased, but the patient should continue on the diet described on p. 687 for several months. It is essential that he should become completely teetotal and should remain so for the rest of his life. It should be pointed out to him that his liver has become abnormally vulnerable, and that even a small quantity of alcohol is a poison for him. He should be warned of the danger of cirrhosis if he does not follow the advice given him. It is remarkable how easily the majority of such patients can become teetotal; fortunately they have none of the craving for alcohol experienced by dipsomaniacs, but only take it because they like it or for the sake of conviviality.

CIRRHOSIS OF THE LIVER

Synonyms.—Portal or Multilobular Cirrhosis; Laennec's Cirrhosis.

Definition.—The portal or multilobular form of cirrhosis of the liver is so much the most common that it is generally described shortly as cirrhosis

of the liver. It is a disease in which degeneration of the hepatic cells occurs in association with fibrosis spreading from the portal spaces to enclose various numbers of lobules.

Ætiology.—Cirrhosis of the liver is generally fatal about the age of fifty, but a distinct group of cases occurs in childhood. It is three times more common in men than in women, but only slightly more so in boys than in girls. It is more common in individuals who follow a sedentary occupation than in those who lead an active life, and among the poor than the well-to-do, though since the Great War it has become less common among the former and more common among the latter.

A large majority of patients with cirrhosis of the liver have indulged excessively in alcohol; it is three times more common among people connected with the liquor trade than among the general public. Any condition, such as syphilis, amœbiasis and malaria, which can produce hepatitis (*vide* p. 672) predisposes to the development of alcoholic cirrhosis. Cases occur, however, especially in Indians and Egyptians and in children, in which alcoholic excess can be excluded with certainty. Thus cirrhosis is not infrequent among Brahmins, the majority of whom indulge in large quantities of ginger, cardamoms, red pepper and other spices, but never touch alcohol. It is probable, therefore, that excessive indulgence in highly seasoned food, especially when associated with chronic malaria, may lead to cirrhosis. I have seen a typical case with severe ascites in a lady of thirty, who was teetotal, had never suffered from malaria, and had always taken an ordinary diet.

Pathology.—Cirrhosis very rarely develops experimentally in animals as a result of chronic alcoholic poisoning, although fatty changes and occasionally necrosis, with a slight degree of small-celled infiltration, may be produced. It occurs in less than 3 per cent. of drunkards dying from the effect of alcoholism, and its geographical distribution does not correspond with that of chronic alcoholism, cirrhosis being rare, for example, in Scotland and Ireland; and when excessive indulgence in alcohol leads to nervous or cardiac symptoms, cirrhosis of the liver as distinct from alcoholic hepatitis is rare. It is probable, therefore, that alcohol produces cirrhosis of the liver indirectly by leading to gastro-enteritis; the poisons produced in the stomach and intestines are absorbed and pass to the liver. As ordinary gastro-enteritis does not lead to cirrhosis, an additional factor must be present. This is probably the direct poisonous action of alcohol and occasionally of other toxins, such as that of malaria, on the liver cells, which thus become more liable to injury by gastro-intestinal toxæmia.

Cirrhosis of the liver may result from the action of poisons which reach it from the spleen. This is the cause of Banti's disease, in which a terminal cirrhosis of the liver develops in a patient with splenic anæmia, as the liver does not become affected if the spleen is removed at a sufficiently early stage. Thus in a typical case under my care a fragment of liver removed when splenectomy was performed showed no pathological changes.

It is probable that the poisons which cause cirrhosis of the liver lead both to degeneration of the hepatic cells and to irritative hyperplasia of the connective tissue; the degeneration of the hepatic cells is increased by the connective-tissue hyperplasia, which in turn is exaggerated by replacement fibrosis following atrophy of the hepatic cells.

The size of the liver varies greatly; it may be much smaller or much larger than normal. The large liver is due to compensatory hyperplasia of the liver cells and to a less extent to fatty degeneration.

The surface of the liver is irregular. The projections may be as small as those of a granular kidney, but more frequently they give rise to a hob-nailed appearance.

The obstruction to the intrahepatic branches of the portal vein produces a rise in pressure in its tributaries; this results in dilatation of the collateral circulation which normally exists between the portal and general venous systems. This compensatory circulation is carried out by the following groups of vessels.

1. An anastomosis may develop within the liver between the branches of the portal vein and the intralobular veins. Large branches pass from the liver and its capsule to the phrenic and intercostal veins, where the liver and diaphragm are uncovered by peritoneum. Occasionally a single large vein passes from the liver in the falciform ligament by the side of the obliterated umbilical vein to join the veins of the abdominal wall at the umbilicus; the subcutaneous veins around and above the umbilicus are consequently dilated, and a large bunch of dilated veins—the caput Medusæ—may form at the umbilicus.

2. The gastric veins anastomose with the œsophageal veins, which open into the azygos veins; the veins in the lower end of the œsophagus may become greatly dilated.

3. The inferior mesenteric vein communicates through the superior and middle hæmorrhoidal veins with the inferior hæmorrhoidal vein, which is a branch of the internal iliac vein; this might be expected to give rise to hæmorrhoids, but they are hardly more common among patients with cirrhosis than in individuals with healthy livers.

4. The veins of Retzius unite the radicles of the portal veins in the intestines and peritoneum with the inferior vena cava and its branches. These include the retro-peritoneal veins, which are often greatly enlarged, especially in the neighbourhood of the kidneys.

Symptoms.—About 50 per cent. of patients with cirrhosis of the liver die from some intercurrent disease or accident. Such cases are generally described as latent; but in the majority symptoms due to the condition were probably present before death, and the fatal result of the intercurrent disease or accident was often due to the diminished power of resistance to toxæmia which results from cirrhosis. In some cases, however, the disease may be genuinely latent, owing to compensatory hyperplasia of the liver cells and to the development of an efficient collateral circulation between branches of the portal vein and systemic veins.

In a large majority of cases the symptoms caused by cirrhosis are preceded by those of pre-cirrhotic hepatitis, which have already been described (p. 680), and alcoholic gastritis has generally been present for many years. The patient habitually wakes in the morning with a feeling of nausea and no desire for breakfast; violent retching often occurs, and he then vomits a small quantity of alkaline watery fluid, after which some bile-stained mucus may appear. A sense of uncomfortable fullness is also felt in the epigastrium after other meals, and the nausea and vomiting may recur. The appetite is poor, and there is a special repugnance for meat. When cirrhosis develops,

the symptoms due to catarrh are exaggerated by the congestion of the gastric mucous membrane caused by portal obstruction; this leads to the secretion of still more mucus, and by preventing absorption of gas leads to flatulence, which aggravates the feeling of distension already present. Flatulence is a constant early symptom and is the earliest sign of portal congestion; it is "le vent avant la pluie."

The complexion is generally sallow and bloated with dilated capillary or arterial angiomata, especially over the nose and cheeks. In the later stages the face is drawn, the cheeks and eyes are sunken, and the conjunctivæ are congested and often slightly tinged with bile. The skin of the body is dry and inelastic; numerous spider angiomata appear on the face, neck and back as the disease progresses, and red or purple areas of skin may be produced by the uniform distension of small venules. Purpura and various forms of erythema may occur.

The tongue is flabby and furred, the gums readily bleed, and pharyngitis is common owing to chronic irritation by alcohol. The breath is often offensive as a result of oral sepsis.

The patient is generally constipated, but attacks of diarrhœa may occur, especially during the last few weeks of life.

In a large proportion of cases the liver is enlarged. Its lower border can generally be felt below the costal margin in the right nipple line; but ascites and occasionally flatulent distension of the intestines or obesity may render it impalpable. It is always abnormally firm; its edge can consequently often be felt even when it is not enlarged. In rare cases an enlarged liver can be observed to shrink as the disease progresses until it ceases to be palpable, and after death it may be found to be considerably smaller than normal. The irregular surface of the liver can occasionally be recognised by palpation. The liver is insensitive in contrast with its tenderness in pre-cirrhotic alcoholic hepatitis.

Discomfort is often felt in the right hypochondrium, but pain only occurs if the disease is complicated by an attack of perihepatitis.

In about 35 per cent. of cases jaundice occurs. It is generally slight, and is often transient. Even in the absence of jaundice van den Bergh's test may give a positive indirect reaction with a delayed or biphasic direct reaction, or more rarely a direct reaction, probably caused by obstruction to the common bile-duct resulting from duodenal catarrh.

In 80 per cent. of cases the spleen is enlarged. Owing to its hardness it is easily felt unless it is obscured by ascites or intestinal flatulence, when its enlargement can be recognised with the x-rays. Discomfort or actual pain may result from stretching of the capsule if rapid enlargement occurs; more frequently it is due to perisplenitis. When both the liver and spleen are much enlarged, the left lobe of the former may overlap the latter.

Hæmatemesis occurs in about 25 per cent. of all cases of cirrhosis. It is generally an early symptom, and is often the first indication of the presence of serious disease, though it is generally preceded by symptoms of gastritis. It is uncommon after ascites has developed. Occasionally it is directly preceded by a period of increased indigestion, which may be associated with fever and enlargement of the spleen; in such cases the patient often feels more comfortable and the spleen diminishes in size after the hæmorrhage. The hæmatemesis generally takes the form of a single large hæmorrhage;

but sometimes a smaller quantity is vomited during the next few days. It is generally repeated only after a considerable interval. The blood collects slowly in the stomach and often passes into the intestine, causing mælena without hæmatemesis. When a considerable quantity has collected in the stomach, the distension causes it to be vomited; small quantities are not brought up unless vomiting occurs from some independent cause. The blood collects more slowly than in gastric ulcer and is therefore generally more clotted and darker, as there is more time for digestion to occur; for the same reason fainting occurs less frequently. Death from hæmatemesis is very unusual in cirrhosis and accounts for less than 5 per cent. of the mortality.

In the majority of cases the hæmorrhage is a result of rupture of varicose œsophageal veins, which form in the development of the collateral circulation. The dilated veins occur in the lower 3 inches of the œsophagus, which is generally also inflamed, and there may be erosions or very superficial ulcers present. The blood runs into the stomach, though in severe cases it may well up directly from the œsophagus. In rare cases the blood comes from the congested pharynx, being swallowed and then vomited. Lastly, hæmorrhage may occur from minute erosions secondary to acute gastritis, sometimes associated with varicose veins. The erosions are very difficult to discover post mortem, and possibly in some cases there is no actual loss of surface, the hæmorrhage corresponding with the bleeding which occurs from other mucous membranes and under the skin as a result of the toxæmia.

Epistaxis is common. The hæmorrhage generally comes from a point on the anterior part of the septum. In the late stages oozing from the nose may occur, as well as from the gums, lungs, kidneys and uterus, as a result of the toxæmia caused by hepatic insufficiency, and small hæmorrhages often occur under the skin. Hæmoptysis, however, is generally due to the cirrhosis being associated with pulmonary tuberculosis.

Ascites is present in most cases of cirrhosis which run their full course; it is a late symptom in uncomplicated cases, and is often absent if the patient dies from some independent cause or from hæmatemesis at a comparatively early stage. The onset is generally gradual, but it occasionally develops suddenly after a blow on the abdomen, a chill, or an acute infection; it is also acute in portal thrombosis. It sometimes disappears spontaneously shortly before death.

Ascites is due in part to portal congestion, as the intrahepatic branches of the portal vein are compressed, some being completely obliterated; occasionally others are thrombosed, and in rare cases thrombosis of the portal vein itself occurs. This is not the sole cause of ascites, as the fluid may collect with extreme rapidity instead of *pari passu* with the changes in the liver, and it is often absent when the portal pressure is high, as shown by the occurrence of hæmatemesis; moreover, it is often present when the collateral circulation is well developed, although this should prevent it. In uncomplicated cases the ascites is probably always in part due to the lymphagogue action of toxins normally destroyed by the liver, which increase the flow of fluid into the peritoneal cavity by injuring the vessel walls. In many cases ascites is a result of chronic perihepatitis, or of more generalised chronic peritonitis, which may be due to irritation of the peritoneum by toxic substances present in the ascitic fluid.

The ascitic fluid is clear and sometimes slightly bile-stained. Its reaction is alkaline, its specific gravity between 1008 and 1015, and a large proportion of the cells it contains are endothelial. When the ascites is due to chronic peritonitis the specific gravity is greater than 1015, more albumin is present, flakes of fibrin may form on standing and polymorphonuclear cells are found. When 50 per cent. or more of the cells are lymphocytes, tuberculous peritonitis is probably present. In rare cases the ascites is chylous or chyloform; still more rarely it is hæmorrhagic.

Edema of the ankles is frequent, but it is rarely very marked, though occasionally it spreads up the legs to the abdomen and back. It may develop before or at the same time as the ascites, in which case it must be toxic in origin, but most frequently it follows it and is caused by pressure of the ascitic fluid on the inferior vena cava and the abdominal lymphatics; it rapidly diminishes when the abdomen is tapped.

Muscular weakness and loss of energy may be the earliest symptoms; they are constant in the late stages. The muscles are flabby and atrophied, and marked wasting of the whole body occurs.

The urine is diminished in quantity and the specific gravity is high. It is very acid and high coloured, and a large deposit of urates generally forms on standing. It contains excess of urobilin, but even when slight jaundice is present bile-pigment is often absent. In the late stages the percentage of nitrogen excreted as ammonia increases at the expense of urea; this is due to ammonia being required to unite with the excess of organic acids present, and not to inability of the liver to form urea, as ammonia given by the mouth is still excreted as urea. In the last days of life leucin and tyrosin are sometimes found.

Albuminuria is occasionally present as a result of intestinal toxæmia, granular kidney or, much more rarely, chronic parenchymatous nephritis, or congestion of the kidneys from heart failure. Glycosuria is rare, as the glycogenic function of the liver is maintained to a certain extent even in advanced cases, but the lævulose test for hepatic efficiency shows considerable impairment throughout the course of the disease.

The blood pressure is generally low, and in the later stages the heart may be dilated and the pulse rapid. The blood is generally normal, except when severe hæmorrhages have led to secondary anæmia. I have seen two cases in which the achlorhydric gastritis caused by chronic irritation of the stomach by alcohol led to the development of typical Addison's anæmia.

The temperature is often raised in rapidly progressing cases apart from complications such as tuberculosis and infective endocarditis.

In the late stages of cirrhosis the toxæmia which results from hepatic insufficiency gives rise to restlessness, irritability and low, muttering delirium, and finally to coma.

Nervous symptoms may also be present as a direct result of chronic alcoholism. Delirium tremens may follow a drinking bout and occasionally hæmatemesis; slight mental disturbance and muscular tremor are not uncommon, but alcoholic neuritis is a rare complication.

Active tuberculous disease is found more frequently in patients dying with cirrhosis of the liver than with other diseases. This is probably due to the diminished resistance to tuberculous infection caused by chronic alcoholism. The lungs are most often affected, phthisis being the cause of

death of 15 per cent. of cases of cirrhosis, and tuberculous pleurisy is not uncommon. Either the cirrhosis or the phthisis may give rise to no characteristic symptoms, being only discovered at the autopsy.

Tuberculous peritonitis is found in 10 per cent. of cases; the ascites which it produces is often thought during life to be due to the cirrhosis. The lungs are generally also involved. The majority of cases of tuberculous peritonitis in adult males are associated with cirrhosis.

Diagnosis.—A regularly enlarged, hard liver in an alcoholic individual, in whom the *lævulose* test shows the presence of hepatic insufficiency, especially if symptoms of gastritis are present, is generally due to cirrhosis. The occurrence of hæmatemesis, enlargement of the spleen, slight jaundice or simply a positive van den Bergh reaction, makes the diagnosis still more probable. The enlarged hard liver, which is produced by the chronic venous congestion in heart failure, may be difficult to distinguish from cirrhosis if the patient is seen when the heart is no longer failing. A history of heart failure with pain in the hepatic region and any evidence of existing heart disease point to congestion. The difficulty is greatest when the patient is alcoholic and the heart failure is the result of alcoholism. In such cases I have always found the ankle-jerks are absent when congestion is the cause, the heart failure being apparently due in part to vagal neuritis, whereas the ankle-jerks are almost always present and there is rarely any other evidence of latent neuritis when the enlargement of the liver is caused by cirrhosis.

The diagnosis from syphilis and from malignant disease of the liver is discussed elsewhere (p. 692 and p. 697).

Splenic anæmia with hæmatemesis can be distinguished from cirrhosis by the much greater enlargement of the spleen and the presence of leucopenia. It must, however, be remembered that cirrhosis of the liver always develops sooner or later in untreated splenic anæmia.

The symptoms in the last stages are often indistinguishable from those of uræmia, and the diagnosis may be very difficult in the absence of a full history; but a high blood pressure, increased blood urea, albuminuric retinitis or the presence of a large quantity of albumin with casts in the urine would prove that uræmia is present.

Prognosis.—If an individual with cirrhosis permanently gives up alcohol in the pre-ascitic stage, there is a good chance that the disease will not progress and that his symptoms will disappear. Even the damage done to the liver can be repaired to some extent by hyperplasia of its cells, a large liver being therefore a favourable sign, and the danger of hæmatemesis, together with the other ill-effects of portal congestion, may be overcome by a sufficient development of the anastomoses between the portal and general venous systems.

Much, therefore, depends upon the patient's character, as, if he is unable to control his desire for alcohol, the disease is certain to advance to a fatal issue. The younger the patient the more chance there is for functional compensation to occur, but the prognosis is always bad in children. However completely latent the disease may become, much of the damage to the liver is of course permanent, and the patient's power of resisting acute infections and all other diseases is materially reduced.

Hæmatemesis in itself is not a serious symptom, as it is very rarely fatal.

When ascites is present, if it is due to the cirrhosis, the prognosis is very

bad, and the patient rarely survives the performance of paracentesis on more than two or three occasions. If, however, it is due to chronic peritonitis, it is much less serious, and the accumulation of fluid may eventually cease.

Fever is a serious symptom, as it indicates rapid advance of the disease or the presence of some complication. The development of the typical cirrhotic facies, together with loss of subcutaneous fat and atrophy of the skeletal muscles, is a serious symptom. When the patient becomes drowsy death is almost certain to follow rapidly, but I have seen complete restoration to health occur in a semi-comatose, tremulous, apparently moribund man, who had drunk champagne in great excess for many years but remained completely teetotal after recovery from the acute illness. Multiple hæmorrhages under the skin or from the mucous membrane are of equally serious import.

The prognosis is much aggravated if the kidneys are diseased and unable to excrete the excess of poisons present in the blood as a result of hepatic insufficiency.

In rare cases the disease runs a subacute course, death occurring within a few months of the onset of symptoms. Such cases are most frequent in comparatively young adults who are heavy drinkers. The liver is painful and tender, fever is present, emaciation is rapid, and multiple hæmorrhages are likely to occur. Pathologically the subacute cases can be regarded as examples of subacute necrosis of the liver.

Treatment.—Alcohol must be absolutely prohibited for the rest of the patient's life, and no medicine containing alcohol should be prescribed. Curries, pickles, ginger, all highly seasoned food, vinegar, mustard, pepper, high game and ripe cheese must be permanently avoided.

Apart from these restrictions, the diet in the early stages should be that required for the treatment of the associated chronic gastritis. In the later stage, when symptoms of hepatic insufficiency are present, the diet should consist entirely of milk, milk foods, vegetable purées and fruit, and even when improvement occurs very little animal food should be allowed.

Gastric lavage is often useful for the gastritis; as this improves, free hydrochloric acid generally returns, but if permanent achylia has developed, dilute hydrochloric acid should be taken with water as a beverage during meals (p. 578). The bowels should be kept regular by means of Epsom salts. No other drugs are required in uncomplicated cases. The treatment of the gastritis, ascites and hæmatemesis is considered elsewhere.

The regular life led at a spa, such as Harrogate or Vichy, combined with the use of a mild aperient water, is often very beneficial.

The drowsy toxæmic condition of the late stage should be treated by means of normal saline solution given by the rectum, or, if it is not retained, subcutaneously. If the urine contains diacetic acid, sufficient sodium bicarbonate should be administered to keep the urine neutral and large quantities of glucose should be given.

HÆMOCHROMATOSIS

Synonyms.—Pigmentary Cirrhosis; Bronzed Diabetes.

Ætiology and Pathology.—Hæmochromatosis is a very rare disease,

in which cirrhosis of the liver is associated with the deposition of large quantities of hæmosiderin, an iron-containing pigment, in various parts of the body, especially the liver, upper abdominal lymph glands, pancreas, suprarenal glands and skin, but very little in the kidneys and spleen. The deposition of pigment is associated with ordinary multilobular cirrhosis of the liver and cirrhosis of the pancreas, and the latter, by involving the islands of Langerhans, may give rise to diabetes mellitus. It occurs in about 7 per cent. of cases of cirrhosis of the liver in males and hardly ever in females. There is no excessive hæmolysis; the quantity of iron deposited is much greater than in hæmolytic anæmias, in which the excess of iron is chiefly in the liver and kidneys, whereas in hæmochromatosis it is chiefly in the liver, pancreas, and abdominal glands, to which it passes from the liver and pancreas.

The disease is extremely chronic. In advanced cases 30 grms. of iron may be deposited in the body compared with the normal of 0.3 grm.; as the ordinary daily intake of iron in the food is about 10 mgrms. it would take 3000 days to accumulate, even if no iron were ever excreted. There must clearly be a failure in the elimination of iron, but it is unknown whether this is primary or the result of excessive deposition. Possibly the damaged liver cells are affected by the unknown toxin responsible for the cirrhosis in such a way that they are incapable of dealing with the iron which comes to them in the food; it is consequently deposited in the cells of the liver and other organs as hæmosiderin. It is, however, equally likely that the cirrhosis of the liver, like that of the pancreas and lymphatic glands, is secondary to the excessive deposit of iron pigment, which in any case must aggravate the cirrhosis.

The theory that hæmochromatosis is due to chronic copper poisoning has been proved to be untenable.

Primary carcinoma of the liver seems to occur in hæmochromatosis somewhat more frequently than in simple cirrhosis of the liver.

Symptoms.—The symptoms are those of cirrhosis and diabetes associated with pigmentation. The liver and spleen become progressively larger; ascites may occur and the subcutaneous veins are sometimes enlarged. The skin is generally pigmented a slaty colour, especially in the exposed parts of the body. The lesion of the suprarenal cortex may give rise to symptoms of Addison's disease, the pigmentation of the skin being sometimes due to melanin and not to hæmosiderin. In the rare cases in which no pigmentation is present the nature of the disease is only discovered after death. In most cases severe diabetes with acidosis appears within a year of death, sometimes acutely, but it may be absent to the end.

Diagnosis.—The disease can only be diagnosed with certainty when pigmentation, diabetes and cirrhosis are associated together. When two of these conditions are present alone, a definite diagnosis is impossible. It can, however, be made with a considerable degree of probability if well-marked bronzing is associated with cirrhosis even in the absence of diabetes.

Prognosis.—So long as no diabetes is present the prognosis is not necessarily worse than that of uncomplicated cirrhosis, but the onset of diabetes is always a very grave event.

Treatment.—The treatment is that of cirrhosis and diabetes.

BILIARY CIRRHOSIS

A condition has been described under the name of Hanot's biliary cirrhosis, which is said to affect children and young adults, often several in a family, and to be characterised by the enlargement of the liver and spleen, with chronic jaundice and febrile attacks, but rarely ascites. Though I gave the usual description of the disease in the earlier editions of this book, I have never seen a case which could be accurately described as biliary cirrhosis, and I am exceedingly doubtful whether such a clinical entity exists. Even in France, where it was first described, it is now said to be exceedingly rare. The term has probably been used to include cases of splenic anæmia with cirrhosis (Banti's disease), acholuric jaundice, ordinary cirrhosis associated with infective cholangitis, and very chronic cases of infective cholangitis.

SYPHILIS OF THE LIVER

CONGENITAL SYPHILIS

Ætiology and Pathology.—The liver is affected in quite 50 per cent. of infants with congenital syphilis. This great frequency is probably due to the *Spirochæta pallida* passing through the placenta and the umbilical vein direct to the fetal liver, which is the first organ it reaches, and which is consequently found to contain it in larger numbers than any other organ.

Congenital syphilis produces diffuse changes in the liver very different from the focal lesions of acquired syphilis, except in rare cases occurring in later childhood, in which caseous gummata are found. The liver is smooth and uniformly enlarged and is firmer and paler than normal. The changes are due to intercellular cirrhosis, the result of diffuse infiltration with embryonic connective-tissue cells between the individual liver cells. These may be associated with small collections of round cells, or miliary gummata, which resemble tubercles when seen by the naked eye.

The spleen is generally enlarged and hard. Diffuse small-celled infiltration or fibrosis may be found in the kidneys, pancreas, testes, suprarenal glands and lungs.

Symptoms.—Symptoms pointing to disease of the liver are not often present in infants with congenital syphilis; but on examination the liver and spleen are found to be enlarged and abnormally firm. The liver normally extends farther down in young children than in adults owing to its relatively larger size and the more horizontal position of the ribs. Only a very definite enlargement of the liver can, therefore, be regarded as important in the absence of other evidence of congenital syphilis. The liver may be tender, and in very rare cases a localised gumma is felt. Jaundice is rare; it may be present from birth or, less frequently, it develops a few weeks later.

Diagnosis.—The diagnosis is generally easy owing to the well-marked signs of congenital syphilis present in other parts of the body. In the absence of such evidence the diagnosis must be made from rickets, tuberculosis and gastro-intestinal infection, and, when jaundice is present, from the other more common causes of icterus neonatorum (p. 666). In doubtful cases the Wassermann reaction settles the diagnosis.

Prognosis.—The prognosis depends upon the general condition of the infant. The disease is less amenable to anti-syphilitic treatment if the liver and spleen are greatly enlarged, and if hæmorrhages occur or jaundice is present. The prognosis in delayed congenital syphilis is less favourable than in acquired syphilis owing to the changes being generally more widespread.

Treatment.—The treatment is that of congenital syphilis.

ACQUIRED SYPHILIS

1. *Secondary Syphilis.*—Jaundice occurs in about $\frac{1}{4}$ per cent. of cases of syphilis at the same time as the roseola and enlargement of glands. It is probably due to obstruction of the small intrahepatic bile-ducts, caused by hepatitis, the result of poisoning with the syphilitic virus (p. 672). The onset is sudden, and the jaundice is not accompanied by any gastro-intestinal or general symptoms. The liver is slightly enlarged. It is very important to distinguish true secondary syphilis of the liver from the toxic jaundice which occasionally results from the treatment of syphilis with organic arsenical preparations (pp. 201, 407).

Recovery is generally rapid with anti-syphilitic treatment. In very rare cases, especially in females, the jaundice becomes more intense and is accompanied by nausea, vomiting, ascites and œdema, and symptoms of severe toxæmia; the liver is at first enlarged and tender, but later becomes small. The final picture is that of acute necrosis of the liver, and this condition is found after death, the *Spirochæta pallida* being present in great numbers throughout the liver.

2. *Tertiary syphilis.*—**Ætiology.**—Gummata are found in only 0·3 per cent. of autopsies; but in more than half of the cases in which other active syphilitic lesions are found the liver is affected.

Syphilis affects the liver three times as frequently in men as in women. The disease is generally discovered between 10 and 20 years after infection, but in rare instances it has occurred within a year.

Pathology.—In the early stages a mass of pink syphilitic granulation-tissue, sharply separated from the healthy liver, is found; necrosis soon occurs in the centre, which becomes yellowish-white. The caseous mass is later surrounded by a fibrous capsule; as this contracts, the liver becomes more and more deformed. The capsule of the liver in the neighbourhood of a gumma is thickened, and adhesions often develop between it and the adjacent organs, the diaphragm and anterior abdominal wall. Unless they are very large, gummata are slowly absorbed till they may finally be represented by nothing more than scars, from which fibrous tissue radiates into the capsule. Gummata are generally multiple; much less often a large part of the liver is diffusely infiltrated. The right lobe and anterior surface are most commonly affected. The condition is often associated with some degree of diffuse syphilitic hepatitis, which produces cirrhotic changes in long-standing cases. This is particularly likely to be the case if the patient is alcoholic or if he has been treated with arsphenamine for primary and secondary syphilis.

Symptoms.—Gummata and cicatrices are sometimes found after death without having led to any symptoms. The nature of the symptoms they

produce depends upon the size, extent and position of the lesions. Before any localising symptoms appear the patient often complains of general ill-health, which is often associated with gastro-intestinal symptoms. The first symptom pointing to disease of the liver is generally pain in the right hypochondrium, the result of perihepatitis over a gumma. The pain may radiate to the right shoulder and is sometimes associated with local tenderness.

Irregularities on the anterior surface of the liver produced by gummata and by the contraction of cicatrices are easily palpable. The diagnosis from malignant disease can be made by the presence of a positive Wassermann reaction and the rapid disappearance of a gumma with anti-syphilitic treatment; jaundice and ascites are much more common in malignant disease, in which the constitutional symptoms are generally more severe, and there may be evidence of a primary growth in some other situation. In hydatid disease the liver is smooth apart from the tumour itself, but in syphilis it is often irregular, owing to the contraction of cicatrices. The presence of eosinophilia points to hydatid disease. A gumma near the gall-bladder or in the left lobe of the liver may simulate a growth of the gall-bladder or of the stomach respectively.

Irregular fever sometimes occurs. The general symptoms may simulate pyelephlebitis, tuberculosis, typhoid fever or malaria, but they generally disappear under anti-syphilitic treatment. In rare cases an infected gumma may break down, when the symptoms and sequelæ do not differ from those of other forms of hepatic abscess.

Jaundice is infrequent in syphilis of the liver, but it is occasionally produced by the pressure of a gumma or of a syphilitic cicatrix; in very rare cases this is associated with attacks of pain indistinguishable from biliary colic due to gall-stones.

Ascites is uncommon, and I have only seen one case in which it was severe and recurred rapidly after paracentesis. It may result from pressure of gummata or cicatrices on the intrahepatic branches of the portal vein, or less frequently on the vein itself in the portal fissure, in which cases thrombosis is likely to occur; it may also result from constriction of the hepatic veins or from perihepatitis over gummata, and much less frequently from universal perihepatitis or widespread chronic peritonitis. In rare cases the fluid is chyloform or hæmorrhagic.

When a gummatous liver is associated with lardaceous disease, the clinical aspects of the latter may be so prominent that the presence of a gumma is overlooked. The liver and the spleen are enlarged, ascites and œdema are present, and the urine contains albumin and casts. It must be remembered that similar evidence of renal disease occurs in syphilitic nephritis apart from lardaceous disease; the former, unlike the latter, may rapidly improve with specific treatment. Apart from the splenic enlargement caused by lardaceous disease a condition indistinguishable from splenic anæmia with secondary cirrhosis of the liver may be associated with syphilis; but it does not respond to specific treatment, though recovery generally follows splenectomy.

Diagnosis.—The possibility of syphilis should always be remembered in obscure hepatic disorders. Apart from a history of infection and the presence of other syphilitic lesions, the Wassermann reaction should always be tested in doubtful cases. As, however, infection with syphilis does not prove that

every lesion present is syphilitic, the final proof of the nature of the disease is only obtained if great improvement or complete recovery results from anti-syphilitic treatment. The diagnosis from cirrhosis of the liver is suggested by the greater irregularity in the enlargement of the liver. Hæmatemesis, dilated veins on the abdominal wall, jaundice and symptoms of gastritis are much more common in cirrhosis, and the nutrition suffers at an earlier stage than in syphilis of the liver.

Prognosis.—The prognosis of syphilitic lesions of the liver is good if treatment is actively carried out at an early stage. In the rare cases in which the symptoms are due to pressure exerted by cicatrices and not by gummata little or no improvement can occur.

Treatment.—As soon as the possibility of syphilis is recognised, large doses of iodide should be given. I have very rarely found ill results follow the administration of as much as 60 grains of potassium iodide every 6 hours; a patient is more likely to suffer from iodism if the dose is gradually increased from a small quantity than if full doses are given at once. Mercury should also be given, but no organic arsenical preparation should be used because of the danger of toxic jaundice occurring as a result of its action on the already damaged liver cells.

HYDATID OF THE LIVER

Ætiology and Pathology.—Hydatid disease is produced by swallowing the ova of the echinococcus or hydatid worm (see p. 354). Food may be contaminated by the fæces of infected dogs, or infection may occur directly if an individual touches the tongue or muzzle of a dog, which has been soiled with eggs from the fæces or anus of another dog. The frequency of the disease thus depends upon the number of infected dogs in a district. It is most common in Iceland and in parts of Australia; it also occurs in England, France and parts of Germany and Russia, but it is almost unknown in North America, except among foreigners.

When the eggs are swallowed, the embryos set free by digestion of the egg-shell pass through the walls of the stomach or small intestine into the radicles of the portal vein, by which they reach the liver, where they are generally arrested. The embryo now forms a small cyst, with an internal, nucleated, protoplasmic layer (the endocyst) and an external "cuticular membrane." The reaction in the surrounding tissues results in the formation of a fibrous capsule. After a time a dozen or more buds project from the endocyst, and develop into daughter cysts, identical in structure with the mother cyst; these soon separate from the endocyst of the mother cyst and become free.

The fluid in the cyst is clear or very slightly opalescent, with a specific gravity between 1·005 and 1·011. It contains chlorides, phosphates, traces of sulphates and succinates, and some unknown toxic substances, but only occasionally traces of albumin or sugar. Hooklets and less often hydatid heads may be found in the fluid.

The liver is involved in 60 per cent. of cases of hydatid disease in man; a single cyst is generally present, but there are occasionally multiple cysts, or single ones may develop in more than one organ.

Symptoms.—The patient remains in good health until the weight of the cyst, its pressure on surrounding parts, or the occurrence of a complication, such as rupture or suppuration, causes symptoms. A hydatid cyst of the liver may remain latent and be discovered only after death or in the course of a routine examination of the abdomen in a patient without abdominal symptoms.

The increasing size of the liver may give rise to a sensation of weight and fullness in the right hypochondrium, and pain may be felt in the right shoulder. I have only once seen jaundice caused by pressure on the bile-ducts, and never ascites by pressure on the portal vein, or œdema by pressure on the inferior vena cava, though both occur in exceptional cases.

A small cyst may rupture into the biliary passages: intense jaundice results, and the patient generally develops suppurative cholangitis. A large cyst may burst into the general peritoneal cavity, especially after a blow on the abdomen. Symptoms of an allergic character may result, especially severe urticaria, erythema and pruritus. Less frequently there may be diarrhoea and vomiting, and dyspnoea, sometimes of an asthmatic character. In rare cases convulsions, collapse and cardiac failure may occur and end fatally. Rupture into the stomach or intestines may lead to spontaneous recovery.

The upper part of the right side of the abdomen and lower part of the thorax become prominent when the cyst is large. If the cyst reaches the front of the liver it becomes palpable in the hypogastrium. When it projects from the under surface, the liver is pushed forward and it may simulate a large gall-bladder or a renal tumour. A cyst near the convexity pushes the diaphragm upwards and may compress the lung and simulate a pleural effusion. In such cases the irregularity in the upper surface of the liver can be recognised with the X-Rays. When deeply embedded in the liver, it produces a more general expansion and no local tumour is palpable. The tumour is generally tense and elastic. In rare cases, of which I have only seen two, percussion of the middle finger, when the left hand is placed flat over the cyst, produces a peculiar vibration—the hydatid thrill—which is almost pathognomonic. It does not, however, depend upon the presence of daughter cysts, as it has been observed in their absence and very exceptionally in other tense cysts.

Bacteria may invade the fibrous capsule and multiply between it and the cuticular membrane, with the result that the nutrition of the hydatid is impaired and the parasite dies. Its death results in a change in the cuticular membrane, which, when healthy, is impervious to bacteria and leucocytes, but now allows them to pass into the fluid, which acts as an excellent culture medium and gradually becomes filled with pus cells. Symptoms of hepatic abscess are now present, and the abscess may finally rupture into the general peritoneal cavity, stomach or intestines.

Diagnosis.—The discovery of a tumour of the liver should lead to a consideration of cancer, syphilis and hydatid cyst. The general health is greatly affected in the first, comparatively little or not at all in the second and third. In cancer and syphilis the tumour is likely to be irregular and multiple; in hydatid it is a uniform round swelling, and most frequently only one can be felt. The two former are hard and obviously solid, while the latter is elastic, and in rare cases the characteristic hydatid thrill can be

felt in it. The Wassermann reaction is positive with a gumma and generally negative in the other diseases. Eosinophilia is frequent in hydatid, but in no other liver disease; it was known to have been present for eleven years when a patient, who proved to have a hydatid of the liver, first consulted me. The proportion of eosinophil cells may be enormous. In the case of a boy of 18, in whom the cyst had grown very rapidly and the legs and scrotum had become oedematous, they amounted to 65 per cent. of 16,000 leucocytes per cubic millimetre; the total and differential counts fell to normal within 3 weeks of the removal of the cyst. I have seen two cases of very large tumours of the right suprarenal, which produced a rounded protuberance on the anterior aspect of the displaced liver, closely simulating a hydatid cyst; the diagnosis was made more difficult by the presence of eosinophilia of 15 to 20 per cent. A doubtful diagnosis can sometimes be confirmed by a precipitin serum reaction. Some of the patient's serum is mixed with an equal quantity of stock hydatid fluid; a precipitate forms at 37° C. within 36 hours in 60 per cent. of cases of hydatid, but only very rarely in the serum of individuals with no hydatid. The intradermal injection of sterile hydatid fluid produces a positive reaction in 90 per cent. of cases, and in one case of mine a pyrexial reaction lasting for three days.

Prognosis.—A cyst may continue to grow for as long as 20 years, but the possibility of suppuration or perforation is a constant danger. When it dies, the cuticular membrane folds on itself and may become calcified; its contents dry up and form a mass containing gritty material. It can then cause no further trouble. The prognosis is worst with deeply-seated cysts and cysts situated near the upper and posterior part of the liver owing to their inaccessibility to operation, and, if multiple, one or more of the cysts may escape observation at the time of the operation.

Treatment.—*Prophylactic.*—In places where hydatid disease is common, the drinking water should be boiled, fruit and vegetables should be cooked or washed with boiled water, and care should be taken not to convey infection from dogs to food by the hands.

Surgical.—Hydatid cysts were formerly treated by tapping, but such methods have now been completely superseded by an open operation, in which the fluid is evacuated and as much of the cyst wall as possible is removed; in some cases the latter is very loosely attached and can be pulled out intact. The operation should be performed whenever a hydatid cyst is diagnosed, even if it causes no symptoms, as there is always a danger of serious complications.

CARCINOMA OF THE LIVER

Ætiology and Pathology.—(a) *Primary growths.*—Primary carcinoma of the liver is only found about once in each thousand autopsies, and primary sarcoma is considerably rarer. Primary carcinoma may be derived from the liver-cells (hepatoma) or, much less frequently, from the bile-duct cells (cholangioma); 90 per cent. of the former and 50 per cent. of the latter occur in cirrhotic livers. Primary cancer occurs in about 7 per cent. of patients with cirrhosis, the incidence being fifty times as great as among patients free from cirrhosis. In cirrhosis of the liver the lesion is a progressive one owing

to the continuous action of the toxin, whereas in post-necrotic fibrosis no further destruction of cells takes place after the original illness. Consequently the nodular hyperplasia of the latter never becomes malignant, whereas the progressive compensatory hyperplasia of the former may overstep the normal and take on the autonomous character of a new growth (*cirrhosis carcinomatosa*).

Primary cancer of the liver readily invades the portal vein, along which it spreads in both directions from the point of entry, forming a tree-like cast of the affected part of the portal system. On section the growth-distended vessels give the appearance of a tumour of multicentric origin, and dissemination to other parts of the liver often occurs through the portal system. In 40 per cent. of cases extrahepatic metastases are present; spread by lymphatics may involve glands in the portal fissure, which may press upon the portal vein and bile-ducts, as well as glands elsewhere in the abdomen and chest, and malignant emboli may pass by the hepatic veins to the lungs. After death the cirrhosis is found to be universal and of long standing, whereas the carcinoma appears to be of recent origin. The liver contains numerous nodules of carcinoma, which often reach the surface, but are never umbilicated. The symptoms may be indistinguishable from those of cirrhosis, the liver being normal in size or slightly enlarged. In the latter case, however, nodules can sometimes be felt on the surface. The spleen is often enlarged, and ascites is always present owing to portal obstruction. Pain in the right hypochondrium and jaundice are more common than in uncomplicated cirrhosis.

(b) *Secondary growths*.—Secondary carcinoma of the liver is about thirty times as common as primary carcinoma; it is ten times as common as secondary sarcoma.

Secondary malignant disease occurs most frequently after the age of 50; it is rather more common in women than men, because carcinoma is more common in women, and also because secondary deposits frequently occur in the liver with carcinoma of the breast and female genital organs, but rarely with carcinoma of the lip, mouth or tongue, which are much more common in men than in women.

The most common seat of the primary disease is the stomach, and then in order the colon, oesophagus, pancreas and gall-bladder; it is a common sequel of cancer of the breast and uterus, and may also occur when the primary disease is situated in any other organ. Cancer of the gall-bladder, extrahepatic bile-ducts and the stomach may invade the liver by direct continuity.

Symptoms.—The liver is almost always palpable, as it is enlarged and abnormally hard. It becomes progressively larger until it may be so enormous that it appears to fill the whole abdomen, the right lobe being generally most affected. The liver is irregular in shape, and individual nodules of growth are often felt to be umbilicated or depressed in the centre. Deposits of growth may be felt at the umbilicus and in the falciform ligament near the linea alba. A rub is sometimes heard over part of the liver as a result of perihepatitis.

Persistent pain is generally felt in the right hypochondrium and in the back; it may pass to the right shoulder and occasionally down the arm. It is in part due to stretching of the capsule of the liver, especially when

it grows rapidly, but the most severe pain is due to perihepatitis. Occasionally deep-seated growths, especially if primary, give rise to no pain throughout the illness.

Jaundice is present in 50 per cent. of cases owing to pressure on the main bile-ducts within the liver by the growth or on those in the portal fissure by glands. Jaundice is more frequent and more often severe in secondary than in primary growths, especially when the primary source of the former is in the stomach or gall-bladder, from which it has spread directly to the portal fissure. The fæces sometimes retain their colour, as the jaundice may be due to pressure on the intrahepatic bile-ducts, one or more of which escapes. The jaundice is progressive and persistent, but it occasionally develops acutely with vomiting and pain, the symptoms being indistinguishable from those of biliary colic due to gall-stones.

Ascites is present in 50 per cent. of cases. It is most commonly due to malignant peritonitis or to perihepatitis; it may also be caused by pressure on the capillaries when the liver is extensively infiltrated with growth and by portal thrombosis caused by invasion of the portal vein. The fluid is generally serous, and when jaundice is present it is bile-stained. Extravasation of blood into a superficial nodule may cause it to be hæmorrhagic. In rare cases it is chylous owing to obstruction of a main lymphatic, but more frequently it is chyloform. Perforation of the organ primarily involved or infection without perforation may cause it to become purulent. Oedema of the ankles is present in the late stages as a result of the toxæmia and cardiac weakness; more widespread dropsy may be caused by pressure upon or thrombosis of the inferior vena cava or some other large vein.

Cachectic symptoms develop as a result of the cancerous toxæmia, and also from intestinal toxæmia, which is no longer kept in check by the antitoxic action of the liver. The patient becomes weaker; the appetite is lost, and there is often a special distaste for meat. The body weight falls progressively, but occasionally the loss of weight due to the general emaciation is more than counterbalanced by the increase in weight of the liver and the accumulation of fluid in the abdomen. The skin is inelastic and sallow, and secondary anæmia develops. It is often possible to see the liver moving slowly up and down with respiration through the wasted abdominal wall.

Fever is often present, especially in rapidly advancing cases, quite apart from the fever which may be caused by infection of the primary growth or of a necrotic secondary deposit. Suppurative cholangitis may be caused by the infection of ducts which have become dilated as a result of obstruction.

Subcutaneous and submucous hæmorrhages may occur, especially if jaundice is present.

The large liver and the ascites may push the diaphragm up and compress the bases of the lungs, which are then likely to become congested, but the main enlargement is always downwards. The growth may spread through the diaphragm and cause hiccough and cough; pleurisy generally develops and often gives rise to a bloodstained effusion, but empyema is rare.

In the late stages the patient becomes somnolent and sometimes delirious. Coma is generally present during the last day or two of life; respiration becomes gradually more shallow, and death comes imperceptibly.

Diagnosis.—A painful and irregular enlargement of the liver is most frequently due to a growth, and the probability is increased if general symptoms of malignant disease are present. If there is evidence of a primary growth elsewhere, the diagnosis can be made with certainty.

The tumour produced by cancer of the liver must be distinguished from one produced by syphilis and hydatid of the liver. The shape of the liver often helps in the diagnosis, and umbilication of a tumour is conclusive evidence of cancer. The general health is much more impaired and the patient is generally older in cancer than in syphilis or hydatid disease. A history of syphilis or evidence of its effects in other parts of the body points to a gumma, and unless a primary growth is discovered the Wassermann reaction should always be tested. Whenever hydatid disease is possible, a differential blood count should be made, as eosinophilia is frequently present, but not in the other conditions. When there is much ascites it may be impossible to diagnose between cirrhosis and cancer, especially if the patient is slightly jaundiced. The abdomen should be tapped so that the liver can be palpated; the irregularities of the cirrhotic liver are so much less marked than those in cancer that they are rarely recognisable through the abdominal wall. The spleen is generally large in cirrhosis but normal in size in cancer, and the liver is rarely very large in cirrhosis. Pain is generally more marked in cancer, and jaundice, when present, is more profound.

The diagnosis of a growth of the liver from a displaced, but otherwise normal liver, from an enlarged liver caused by chronic venous enlargement, lardaceous disease, or the impaction of a gall-stone in the common bile-duct without a previous attack of colic, and from a tumour of the right kidney, or an accumulation of faeces in the transverse colon, ought to cause no great difficulty.

Diagnosis between primary and secondary malignant disease.—In secondary cancer of the liver the primary disease is often latent, especially when it is situated in the stomach or colon. But when a thorough investigation fails to reveal a primary growth elsewhere in the body, if jaundice and ascites are absent and emaciation is slight, a single, rapidly growing tumour of the liver is more likely to be primary than secondary.

Prognosis.—Cancer of the liver is always fatal. The course of primary cancer is very rapid, as it rarely lasts more than four months, and death may even occur within four weeks of the onset of symptoms. The duration of the illness in secondary carcinoma of the liver depends upon the primary disease, death being often due to the latter. If the primary disease has been removed by operation or is latent, death may not occur for a year or even longer after the disease of the liver is discovered; but most cases prove fatal within six months. The disease generally advances steadily, but occasionally it may remain almost stationary for a time and then rapidly progress to a fatal issue.

Treatment.—In very rare cases a primary growth of the liver or a growth invading it from the gall-bladder or stomach has been removed, but the disease has generally recurred, as it is impossible to tell at the time of the operation whether secondary deposits are not present in the deeper parts of the liver. It is never justifiable to operate when it is known that a growth of the liver is present; but if during an operation for cancer of the stomach or gall-bladder the liver is found to be involved only in its

immediate neighbourhood, an attempt should be made to remove the affected parts.

The medical treatment of cancer of the liver is purely palliative, but by means of morphine the patient should be spared pain throughout the illness. An injection of morphine should be given whenever pain is felt, and the dose should be increased as the disease progresses and the patient becomes accustomed to the drug. There is no reason to fear giving very large doses several times in the day, as with their aid patients often feel perfectly happy and comfortable up to the end. Aspirin is also useful, especially in the early stages. The bowels should be kept regular by drugs, such as infusion of senna pods, the dose of which generally requires to be increased as more morphine is given. The patient should be allowed to eat and drink exactly what he likes, and no restrictions should be made on account of the supposed indigestibility of certain articles of food, nor should large quantities of food be forced upon a patient who has no appetite. When the diagnosis has once been made with complete certainty, frequent examinations of the abdomen distress the patient without doing any good. If the distension produced by ascites gives rise to pain, the fluid should be removed.

ARTHUR F. HURST.

DISEASES OF THE PORTAL VEIN

NON-SUPPURATIVE PYLEPHLEBITIS AND PORTAL THROMBOSIS

Ætiology and Pathology.—Cirrhosis of the liver accounts for about 30 per cent. of cases of portal thrombosis, but the latter is so rare that it only occurs in about $1\frac{1}{2}$ per cent. of cases of cirrhosis. Its occurrence in cirrhosis is due to stagnation of blood in the portal vein, associated with sclerosis of the walls caused by the local rise in blood pressure together with infection secondary to intestinal catarrh. Malignant disease of the liver, stomach or pancreas is the next most common cause; invasion of the veins of the affected organ leads to thrombosis, which spreads to the portal vein. Syphilitic changes in the walls of the portal vein and non-suppurative pylephlebitis caused by spread of infection from neighbouring parts may cause thrombosis.

Portal thrombosis may extend throughout the vein and its branches, but more frequently it is localised to the main trunk and one or more intra-hepatic branches or extrahepatic tributaries.

Symptoms.—In the presence of cirrhosis of the liver or intra-abdominal growth, especially if ascites is present, there may be no indication that portal thrombosis has occurred. If, however, the patient is in comparatively good health, sudden occlusion of the portal vein may lead to the rapid development of ascites, hæmatemesis and melæna, and the spleen becomes enlarged. When the splenic vein is occluded, the splenic enlargement is rapid and considerable. When mesenteric veins are suddenly involved, hæmorrhagic infarction results, which leads to intestinal paralysis with severe melæna and early death.

Diagnosis.—The sudden onset of ascites and hæmatemesis with splenic enlargement, with or without evidence of cirrhosis or intra-abdominal growth, is suggestive but far from conclusive evidence of portal thrombosis.

SUPPURATIVE PYLEPHLEBITIS

Synonym.—Portal Pyæmia.

Ætiology.—Suppurative pylephlebitis is almost always secondary to some intra-abdominal inflammatory disease, generally associated with the presence of pus under pressure. Acute appendicitis accounts for nearly half of the cases.

Pathology.—The veins leading from the source of infection to the liver, together with the trunk and intrahepatic branches of the hepatic vein, may all be involved, but the disease is generally less extensive and may be confined by firm clots to a part of the portal vein or one of its branches. The affected veins contain pus and broken-down blood clots. Their walls are acutely inflamed and may give way, leading to the formation of abscesses. Thus a large abscess may develop in the mesentery or behind the pancreas. The liver is almost always involved by extension to the intrahepatic portal branches, or by secondary abscesses formed from infective emboli from the part of the vein primarily affected. Innumerable minute abscesses are present, many of which may coalesce to form a honey-combed appearance or large abscesses. Superficial abscesses may rupture and lead to general or local peritonitis, which may also result from the primary disease. The infection is generally caused by streptococci, staphylococci or *B. coli*, and very rarely *B. typhosus* or *B. dysenteriae*.

Symptoms.—The onset is generally sudden, the symptoms due to the primary disease being complicated by the occurrence of a rigor or pain and tenderness over the liver. The clinical picture is eventually a composite one of the symptoms of the primary disease, sepsis and liver disease, with the frequent addition before death of pneumonia, pulmonary abscesses or empyema, generally on the right side. Evidence of portal obstruction is rarely present. The patient looks anxious and ill; he is sallow, and in about half the cases is jaundiced; the jaundice is generally slight, but may be severe from associated cholangitis. Fever is continuous, intermittent or remittent, leucocytosis is present, and the pulse and respiration are rapid. Rigors, with profuse sweating, are common, especially in the early stages. Uniform enlargement of the liver occurs in about 60 per cent. of cases; it is often considerable. Pain and tenderness are generally present, and a rub may be heard over the liver. The spleen is only occasionally enlarged. Vomiting is common and diarrhoea may occur. Blood cultures are generally sterile.

Diagnosis.—The development of a septic state with rigors and enlargement and tenderness of the liver in a patient with appendicitis or other intra-abdominal disease is suggestive of suppurative pylephlebitis, but a correct diagnosis is rarely made. In amœbic abscess of the liver there is generally a history of dysentery, the progress of the disease is less rapid, and there may be signs of a single abscess instead of a uniform enlargement of the liver. A history of gall-stones is much more common in suppurative

cholangitis than in pylephlebitis, and jaundice appears earlier and is deeper. The diagnosis from a sub-diaphragmatic abscess secondary to appendicitis may be impossible, and the two may be present together. Infective endocarditis with enlargement of the liver and spleen without cardiac murmurs closely simulates suppurative pylephlebitis. Chronic malaria may also give rise to similar symptoms, but can be recognised by examination of the blood and by the improvement which occurs with quinine.

Prognosis and Treatment.—The disease is always fatal, and no treatment is of any avail.

ARTHUR F. HURST.

DISEASES OF THE GALL-BLADDER AND BILE-DUCTS

CHOLECYSTITIS

Ætiology and Pathology.—Cholecystitis results from infection of the gall-bladder, most frequently with *B. coli*, but also with *B. typhosus* and *paratyphosus*, streptococci and staphylococci. The mere presence of bacteria in the bile does not necessarily lead to cholecystitis, just as bacilluria may occur without causing pyelitis. The *B. coli*, which normally inhabits the colon and lower part of the ileum, might theoretically gain access to the gall-bladder by four different channels.

(1) Typhoid bacilli pass from the intestines by the lacteals to the mesenteric glands, from which they are conveyed by the lymphatics to the thoracic duct and thence into the general circulation, a typhoid septicæmia being thus produced. The bacilli are excreted from the blood in the bile by the liver and in the urine by the kidneys probably in every case, but cholecystitis and pyelitis only develop in a comparatively small proportion. There is no doubt that *B. coli* can pass through the healthy bowel wall, but under ordinary conditions it gets no farther than the lymphatic glands, which act as a very efficient filter, and there is no evidence that acute *B. coli* cholecystitis, corresponding with acute *B. typhosus* cholecystitis, ever occurs, or that chronic cholecystitis is ever preceded by a *B. coli* septicæmia. Even in ulcerative colitis, in which the inflamed and ulcerated mucous membrane of the colon might be expected to permit the easy passage of bacteria into the general circulation, neither septicæmia nor cholecystitis occurs.

(2) The portal vein would seem a likely channel for the passage of *B. coli* to the liver and thence in the bile to the gall-bladder without gaining access to the general circulation. But the portal blood is normally sterile and remains so even when the wall of the bowel is damaged, and bacteria injected into the portal vein of animals are not excreted in the bile. In suppurative pylephlebitis, the only condition in which severe infection of the portal vein is known to take place, there is no evidence that the infecting organisms are excreted in the bile, and it is not as a rule complicated by cholangitis or cholecystitis.

(3) It has been suggested that cholecystitis is the result of infection with strains of streptococci having a special affinity for the gall-bladder, which are conveyed to it by the cystic artery from infected teeth, tonsils and other foci. But infection of the gall-bladder with streptococci is much less common

than with *B. coli*, and later investigations have failed to confirm the experiments upon which this theory was based.

(4) Most cases of cholecystitis are probably due to an ascending infection from the duodenum. The duodenum is normally sterile, but in achlorhydria large numbers of *B. coli* are always present and less frequently streptococci. Achlorhydria is found in 25 to 50 per cent. of cases of gall-stones. In the acute gastritis which occurs in food poisoning and influenza and other infections achlorhydria is generally present, although it is only likely to persist in association with chronic gastritis in individuals with constitutional hypochlorhydria. But observations after perforation of gastric and duodenal ulcers show that the stomach and duodenum are invaded by organisms ascending from the colon within a few hours of the appearance of the achlorhydria caused by sympathetic inhibition of secretion following the perforation. It is clear, therefore, that the duodenum may be infected during the temporary achlorhydria resulting from acute gastritis, and the infection may last sufficiently long for ascending infection of the gall-bladder to occur. It is in fact not uncommon for patients with chronic cholecystitis to date their symptoms from an attack of food poisoning or an acute infection which may have been accompanied by achlorhydria, even if the gastric secretion when the patient comes under observation is normal. As acute gastritis is very common and few people pass through life without having one or more attacks, it is easy to understand why cholecystitis is such a common disorder.

Infection of the gall-bladder first leads to inflammation of the mucous membrane, the external appearance of the gall-bladder remaining normal. The inflammation subsequently spreads to the deeper tissues and in some cases the original inflammation of the mucous membrane may then subside. By this time the external appearance of the gall-bladder is always altered, the walls are thick and inelastic, and the cystic lymphatic gland is enlarged and inflamed.

Cholecystitis may be acute, subacute or chronic from the onset. Acute and subacute cases may become chronic, and suppuration or gangrene may occur in a chronically inflamed gall-bladder if a stone becomes impacted in the mouth of the cystic duct. The contents may become purulent in the course of an acute infection without gall-stones, but necrosis is very rare in their absence.

ACUTE CHOLECYSTITIS

Ætiology and Pathogenesis. — Acute cholecystitis occurs in about 1 per cent. of cases of typhoid and paratyphoid fever. Apart from this it is rare unless the cystic duct is obstructed by an impacted gall-stone. Bile is generally only present in the gall-bladder if the contents are examined within a few days of the onset. The wall is thickened and obviously inflamed, and the cystic lymphatic gland is enlarged. When the cholecystitis is secondary to an impacted gall-stone suppuration or gangrene is likely to occur. Suppuration leads to empyema of the gall-bladder: if adhesions have previously formed as a result of chronic cholecystitis the empyema may rupture into the duodenum or colon; otherwise localised or generalised peritonitis results. Necrosis may be localised or general. When localised it is generally secondary to ulceration at the neck of the gall-bladder following impaction of a stone

rupture into the duodenum or the production of a local abscess commonly follows. The whole wall of the gall-bladder may become gangrenous as a result of over-distension from obstruction of the cystic duct or less commonly of the common bile-duct, especially in elderly people in whom the blood supply is deficient. Unless cholecystectomy is promptly performed, general peritonitis is certain to develop.

Symptoms.—Acute pain in the right hypochondrium is the most constant symptom. It often radiates to the angle of the right scapula and less frequently to the right shoulder. The gall-bladder may be felt as an extremely tender tumour, but more frequently the rigidity of the right rectus makes deep palpation impossible. Jaundice only occurs if there is a stone in the common bile-duct or the cholecystitis is part of a general infection of the biliary passages, and a greatly distended gall-bladder may obstruct the common bile-duct. Pyrexia is always present together with polymorpho-nuclear leucocytosis.

The *défense musculaire* often involves the right dome of the diaphragm as well as the right rectus, signs of cedema and congestion of the base of the right lung being present.

In mild cases recovery takes place after a few days, but symptoms of chronic cholecystitis may develop at a later date. In suppurative or gangrenous cholecystitis fatal complications rapidly occur unless an early operation is performed.

Treatment.—Mild cases subside with the physiological rest provided by a lacto-vegetarian diet, the patient being kept warm in bed. In more severe cases, especially if there is a leucocytosis of more than 12,000 cells per cubic millimetre, or if suppuration or gangrene is suspected, an operation should be performed without delay.

CHRONIC CHOLECYSTITIS

Symptoms.—Chronic cholecystitis is the most common organic cause of chronic dyspepsia. The patient complains of intractable indigestion of an irregular character, in striking contrast with the clock-like regularity of the pain in duodenal ulcer. The time of onset and the severity of the pain vary greatly from meal to meal and from day to day; it sometimes begins immediately after food, and at other times it may not come until two or three hours after a meal, or it may only occur in the early part of the night. It is unaffected or only incompletely relieved by taking food and by alkalis. In most cases the patient complains of what he calls flatulence, but this is really only a sensation of fullness, which is not associated with increased fermentation, and only with eructation when it gives rise to aerophagy by causing the patient to make repeated but futile efforts to belch in the hope of relieving his discomfort.

Nausea is common. It may occur on waking, when it is sometimes associated with vertigo, cold sweats or headaches, in which case migraine may be simulated, though the headache is not unilateral. It may be relieved by breakfast, unless eggs are eaten, when it is often aggravated. It is sometimes followed by vomiting, which gives much less complete relief than in ulcer.

Patients with ulcer generally lose all their pain in two or three days if put to bed on a strict diet, but improvement is less likely to follow in cholecystitis;

the dyspepsia may, however, rapidly improve if yolk of egg and other fatty foods are prohibited. Constipation is generally present, but in some cases intermittent or continuous diarrhoea of a mild grade occurs, and in rare instances profuse, watery diarrhoea heralds the onset of an acute exacerbation.

If attacks of biliary colic, whether of the abortive or acute variety, occur in association with symptoms of cholecystitis, gall-stones are probably present.

The discomfort after meals is generally in the mid-epigastrium, but it often extends to the right and may be confined from its onset to the right hypochondrium. It is frequently associated with pain at the angle of the right scapula.

Tenderness of the gall-bladder is the most characteristic sign of cholecystitis. It is best elicited with the patient lying relaxed on his back; the fingers are then pressed beneath the right costal margin in the region of the gall-bladder. The pain is much increased when the fingers are brought into still more intimate contact with the gall-bladder by deep inspiration, which is then sharply arrested. The pain produced in this way is in striking contrast with the absence of tenderness when deep pressure is exerted under the left costal margin or a very short distance to the inner or outer side of the gall-bladder under the right costal margin, though it is not uncommon for a slighter degree of tenderness to be observed over the whole of the lower border of the liver, especially in the immediate neighbourhood of the gall-bladder. Pressure on the gall-bladder may also cause nausea, which may even occur in the absence of pain.

Diagnosis.—The healthy gall-bladder can be visualised with the X-Rays by Graham's method (*cholecystography*). The patient is given a fat-free meal at 6 p.m. the evening before the examination, and at 9 p.m. he very slowly drinks a solution of phenoltetraiodophthalein in half a pint of water. During the following hour he sips water, but after that no further food or drink is allowed until the first examination is made at the fifteenth hour. If the shadow is weak, another radiogram is taken at the eighteenth or twentieth hour. When a sufficiently clear picture has been obtained, a fatty meal, consisting chiefly of buttered eggs or the yolks of two raw eggs, is taken. If the gall-bladder has not filled at the eighteenth hour, an ordinary meal is given followed in six hours by a fat-free meal and a repetition of the whole procedure. Much better results are obtained by this means than by postponing the second examination by one or more days. Occasionally at the first examination the shadow of the gall-bladder is partially obscured by gas or undissolved dye in the colon; in such cases the colon should be washed out with saline solution.

The opaque dye is absorbed and excreted in the bile, in which it reaches the gall-bladder; as no further meals are taken it remains here, and as a result of absorption of water by the mucous membrane it becomes sufficiently concentrated to throw a shadow of the gall-bladder, which can be seen with the X-Ray screen, and a cholecystogram can be taken. A normal gall-bladder gives a homogeneous shadow with a regular outline; it is not tender when directly palpated, and it is freely movable, being quite independent of the shadow of the duodenal bulb, which can be seen simultaneously by giving a small opaque meal. The normal gall-bladder is found to have contracted and evacuated the greater part of its contents an hour after the fatty meal.

In simple cholecystitis the gall-bladder shadow is normal, but the

visualised organ is found to be the seat of the tenderness previously discovered in the supposed position of the gall-bladder. Not infrequently the gall-bladder is found to be in an unusual position, and tenderness, which would not otherwise have been found, can then be elicited. If adhesions have formed, the outline may be deformed, remaining so even when contracted after a fatty meal, and it may be impossible to separate the shadow of the gall-bladder from that of the duodenal bulb visualised by giving a small opaque meal. When the mucous membrane is severely damaged the shadow is either feeble or absent, though this is rare in the absence of gall-stones, and when the muscular wall is involved both filling and emptying may be delayed.

The upper part of the right rectus abdominis muscle is often tender and rigid; tenderness and rigidity of the lowest intercostal muscles may cause impeded respiration and a stitch in the right side of the chest. Tenderness is also sometimes present over the third to the tenth dorsal spines, the muscles to their immediate right and the end of the eleventh rib.

In chronic cholecystitis there is generally no pyrexia, but occasionally the temperature rises to between 99° and 100° F. each evening or during exacerbations of the inflammation accompanied by more marked symptoms.

Whenever cholecystitis is suspected, an attempt should be made to obtain some of the contents of the gall-bladder for pathological examination (*Meltzer-Lyon test*). A sterilised Einhorn tube is swallowed up to the 23-inch mark first thing in the morning before the patient has had anything to eat or drink. The stomach is emptied and washed out with sterile water. The tube is then slowly paid out up to the 28½-inch mark, which allows sufficient length for the duodenum to be reached. Samples are aspirated every quarter of an hour until the comparatively abundant, acid, turbid and colourless fluid present in the stomach is replaced by the very small quantity of neutral or alkaline, clear, and generally bile-stained fluid present in the duodenum. The pylorus is generally passed in less than half an hour, but if delay occurs the sphincter can be made to relax by the introduction of magnesium sulphate. The duodenum is washed out with sterile water, and from 2 to 4 drachms of a 25 per cent. solution of magnesium sulphate are injected through the tube. This causes the gall-bladder and the bile-ducts to contract and the sphincter of the common bile-duct (Oddi's sphincter) to relax. An abundant flow of pure bile rapidly appears; this is aspirated, and the tube is withdrawn. In the absence of gall-bladder disease, the bile never contains any pus cells, epithelial cells, pigment granules or cholesterol crystals, but often a little mucus; it is generally sterile, but a few bacteria may be present if the duodenum has not been sufficiently washed out, especially in cases of achlorhydria, in which the duodenal contents generally swarm with bacteria. In cholecystitis the quantity of mucus is greater than normal, and degenerated columnar epithelial cells and, less frequently, pus cells and pigment granules are present; the bile contains bacteria, most commonly an aberrant form of *B. coli* in pure culture, and rarely streptococci or staphylococci. In two cases of mine *B. typhosus* was isolated—23 and 10 years respectively after typhoid fever. The presence of a liquid yellow lipid material in the gall-bladder contents suggests the presence of a strawberry gall-bladder. If cholesterol crystals are found, gall-stones are generally, but not always, present.

Treatment.—The majority of early cases of cholecystitis can be cured by medical treatment, and great improvement often occurs in very chronic cases. Hexamine is excreted by the bile; whereas it only acts as an antiseptic in acid urine which sets free formalin from it, the presence of bile salts makes it active in bile in spite of its alkalinity (Knott). As a maximal concentration of the drug is required, alkalis should be given simultaneously in sufficient quantity to make the urine alkaline; by this means the production of formalin in the urine is prevented, and large doses can be given without irritating the bladder. A mixture containing 100 grains of hexamine with 100 grains each of sodium bicarbonate and sodium citrate in 1 oz. of water is given three times a day, the first dose after breakfast, the second after tea, and the third after a glass of water or milk on going to bed. The patient should continue to take the 300 grains of hexamine a day until all symptoms have disappeared. It is only rarely necessary to reduce the dose or to omit the hexamine altogether for a few days on account of the bladder showing signs of being irritated. An autogenous vaccine prepared from the *B. coli* or other organism isolated from the bile may help to overcome the infection.

Stasis of bile in the gall-bladder aggravates the infection. It is fortunate therefore that thorough drainage can be assured by the oral administration of magnesium sulphate in concentrated solution when fasting an hour before breakfast. The largest quantity should be given which the patient can take without getting diarrhoea when no other aperient is used. This causes the gall-bladder and bile-ducts to empty their contents into the duodenum through the relaxed Oddi's sphincter. Olive oil in $\frac{1}{2}$ -oz. doses should be taken three times a day half an hour before meals as it has the same effect as magnesium sulphate on the gall-bladder.

If cholesterol crystals or liquid yellow lipid material are found in the bile from the gall-bladder, a cholesterol-free diet should be given. No eggs and nothing made from the yolk of eggs should be allowed. Butter must be used sparingly; cream, cheese, kidney, liver, sweetbread, brain, duck, goose, suet and sausages are not allowed, and as little fat of meat as possible should be taken.

If achlorhydria is present, gastric lavage should be practised in the hope that normal secretion will be restored. If this fails, hydrochloric acid should be given before breakfast and with lunch and dinner, but not during a course of treatment with hexamine, as it makes it difficult to keep the urine alkaline. If hyperchlorhydria is present, belladonna should be given in addition to the olive oil before meals.

Foci of infection in the teeth and tonsils should be looked for and thoroughly treated. If the appendix is diseased, it should be removed, and cholecystectomy should be performed at the same time, even if the external appearance of the gall-bladder is normal, as in many cases of chronic cholecystitis the obvious inflammation is confined to the mucous membrane. Apart from this, the indication for surgery in chronic cholecystitis is the failure of medical treatment after it has been thoroughly carried out for an adequate time. If it is likely that gall-stones are present, it is generally useless to delay operation. In all cases cholecystectomy should be performed in preference to cholecystostomy.

GALL-STONES

Synonym.—Cholelithiasis.

Ætiology.—Clinically gall-stones occur about twice as frequently in women as in men, but they are found post mortem about five times more often in women than men. They are very rare before the age of 15; 75 per cent. of clinical cases occur between 30 and 60, 40 to 45 being the most common age. The incidence is greatest post mortem about 20 years later; gall-stones occur in about 25 per cent. of all women and 7 per cent. of all men dying after the age of 25.

Pathology.—(a) *Infection.*—Infection of the gall-bladder leads to cholecystitis. The agglutinated bacteria, precipitated mucus and cellular debris may form the nucleus of gall-stones if excess of cholesterol or bile-pigment is present in the bile, especially if the flow from the gall-bladder is less free than it should be. The nature and the path of infection have been discussed in the description of cholecystitis (p. 700). Stones may form very rapidly; 25 faceted cholesterol stones, between $\frac{1}{8}$ and $\frac{1}{4}$ inch in diameter, were removed from a suppurating gall-bladder in a patient of mine 68 days from the onset of an attack of typhoid fever; *B. typhosus* was isolated in pure culture from the centre of the stones and the pus.

When gall-stones have once formed, the infection frequently dies out, and the bile, stones and wall of the gall-bladder may be sterile, though the latter always shows signs of old inflammation. In other cases the organisms commonly found in cholecystitis are still present.

(b) *Excess of Cholesterol in the Blood and Bile.*—The majority of gall-stones contain a considerable proportion of cholesterol. Normal blood contains cholesterol, which comes from endogenous and exogenous sources. The endogenous cholesterol is produced by the constant activity of the cortex of the suprarenal glands, and by the periodic activity of the corpus luteum at each menstrual period. During pregnancy the corpus luteum produces a very large quantity of cholesterol, so that the percentage in the blood gradually increases to nearly double and that in the bile to four times the normal. The exogenous cholesterol comes from certain articles of diet; it is abundantly present in eggs and to a less extent in cream, and in liver, kidney, sweetbread and brain. The importance of hypercholesterolaemia in the pathogenesis of gall-stones has probably been exaggerated. Accurate post-mortem statistics show that the greater incidence of gall-stones in females is not due to pregnancy, as the proportion of women with gall-stones who have borne children to those who have not is the same as the proportion among those who have no gall-stones. There is, however, no doubt, that a biochemical factor must be present to explain the development of the large, solitary, pure cholesterol stones, which are occasionally found in perfectly healthy and sterile gall-bladders. Moreover, many patients with gall-stones have an instinctive distaste for eggs and animal fat of all kinds, which may date from childhood, and they know that such articles of diet are exceedingly likely to promote a "bilious attack." It is probable that some constitutional peculiarity in connection with cholesterol metabolism is an important predisposing cause of gall-stones; this would explain

why only a certain proportion of individuals develop stones under apparently similar conditions.

(c) *Biliary Stasis*.—A stone is especially likely to form in the presence of infection and excess of cholesterol in the bile if biliary stasis is also present. This is particularly likely to occur in cholecystitis owing to the partial obstruction caused by the swelling of the mucous membrane of the cystic duct. In some cases there appears to be a congenital or acquired abnormality of the anatomical relations or of the neuro-muscular mechanism of the bile channels, which impedes the evacuation of the bile (*vide* p. 662). Deficient exercise also leads to biliary stasis.

By examining sections of gall-stones it is generally possible to get some idea of the history of their formation. Thus the centre of most is white and consists of pure cholesterol; only after the stone has reached a certain size is there as a rule any deposit of pigment or lime salts resulting from a period of infection. Then there may be a further layer of cholesterol due to a return of hypercholesterolaemia owing to a second pregnancy; then another stratum of pigment and lime salts may form, and so on. A pure cholesterol stone corresponds to a pure oxalic acid or uric acid stone in the kidney, and the presence of pigment and of lime salts corresponds to that of phosphates in a urinary stone. Pure pigment stones are always the result of infection, except in cases of acholuric jaundice, when they are secondary to excessive production of bile-pigment by hæmolysis.

Symptoms.—In rare cases gall-stones may be completely latent. Most frequently their development is preceded and accompanied by continuous or intermittent dyspepsia. These "inaugural symptoms" are sometimes referred to as gall-stone dyspepsia: they are really due to cholecystitis (p. 702) and not to the presence of stones. Abortive attacks of biliary colic may occur independently of or associated with gall-bladder dyspepsia. Typical attacks of severe colic are less frequent. They are commonly preceded by more chronic symptoms and rarely occur without any previous symptoms.

Many patients who suffer from gall-bladder dyspepsia and a few who have no such symptoms complain of short attacks of severe pain, which may occur at any time of the day or night without any obvious cause, such as an indiscretion in diet, although occasionally an attack is the direct sequel of a long railway journey, a drive in a motor-car on a bad road, or violent exercise. Attacks may occur daily or at long intervals, or there may be a series close together followed by a long spell of freedom. The patient may shiver during an attack, although his temperature never rises greatly and often does not rise at all. The shivering is occasionally accompanied by a sensation of "goose-skin," particularly in the epigastrium and right side of the upper part of the abdomen. When the pain is acute, it is impossible to take a deep breath, the attempt producing a "catch" in the right side of the chest, which is very similar to that felt in pleurisy.

Attacks of biliary colic most frequently result from impaction of the stone in the neck of the gall-bladder close to or at the orifice of the cystic duct. They often occur in the night. The attack begins with extremely sudden acute pain in the epigastrium or in the region of the gall-bladder or both; it may pass through to the angle of the right scapula. The violent pain is accompanied by great restlessness, in marked contrast with the

motionless state of a patient with a perforated ulcer, acute appendicitis, or angina pectoris. Some relief may be obtained by pressing upon the abdomen. The patient feels cold, but sweats profusely. Breathing may be difficult, but the presence of definite dyspnoea or faintness, when the pain is high in the epigastrium or still more so if it is substernal, should raise the suspicion of coronary thrombosis as an alternative diagnosis. Nausea and vomiting almost always occur; the vomiting may give some relief. Aerophagy is generally present. The pain commonly disappears with absolute suddenness. The sudden onset and sudden cessation are specially characteristic of gall-stone obstruction in the cystic duct. The temperature may rise a degree or two during the attack, and there may be a slight temporary leucocytosis and albuminuria. Constipation is complete.

Jaundice occurs only when a stone reaches the common bile-duct. Repeated attacks without jaundice are generally caused by a stone of some size becoming impacted in the neck of the gall-bladder. Repeated attacks with jaundice, which may be very evanescent and sometimes completely latent and only recognisable by the temporary presence of a positive direct van den Bergh reaction, indicate the passage of small stones, numerous stones being generally still present in the gall-bladder. The slightest yellow tinge of the conjunctivæ or a trace of bile in the urine is very valuable evidence that an attack of pain of doubtful origin is due to gall-stones.

If a small stone, having traversed the cystic duct and passed down the common bile-duct to reach the ampulla of Vater, remains there owing to the smallness of the lumen of the mouth of the ampulla, a special group of symptoms appears. In two-thirds of the cases one or more stones are also present in the gall-bladder. A stone in the ampulla acts as a ball-valve causing intermittent attacks of colic with incomplete jaundice. Pain is rarely absent; it is occasionally the only symptom. Vomiting is common in the attacks, which are accompanied by fever with chills or severe rigors in 50 per cent. of cases. The jaundice is rarely complete and persistent; it is occasionally absent, but in such cases van den Bergh's test generally gives a positive direct reaction showing that hyperbilirubinæmia is present; in rare cases it is unaccompanied by pain. In the intervals between attacks the patient may appear to be quite well, though a slight degree of jaundice or some residual pain in the gall-bladder region may be present. Sooner or later ascending cholangitis is likely to develop; there is then constant pyrexia with repeated rigors and polymorphonuclear eucocytosis.

Small gall-stones are rarely recognised in the stools. Larger ones are only passed in a very small proportion of cases. It is important to distinguish gall-stones or biliary sand from intestinal sand and concretions produced by drugs or by the administration of large quantities of olive oil. The majority of gall-stones consist of cholesterol and can, therefore, be recognised by being very light and inflammable. The rarest form of stone to be passed is a very small rounded one, which has probably traversed the normal passages during an attack of colic; as it may be the only one, a cure may result. More frequently faceted stones are passed; even if large numbers are found, it is very unlikely that all have left the gall-bladder. Lastly one, or less frequently two or three large stones, which may be formed

by the agglomeration of several smaller ones, may be passed after traversing a fistulous communication between the gall-bladder and duodenum or colon. The fistula may develop very slowly without symptoms after chronic cholecystitis has led to the production of adhesions. More frequently the perforation appears to be sudden and takes place during or after an attack of colic. In other cases the fistula may be caused by the perforation of an empyema of the gall-bladder into the bowel. When a large stone traverses the whole bowel, pain is generally produced at one time near the right iliac fossa owing to obstruction in the terminal ileum. If it passes farther, pain is later felt below the umbilicus and finally in the rectum, from which it may have to be dislodged by the finger. The complete passage may take from 1 to 8 days.

It is generally impossible to palpate the gall-bladder during an attack of acute pain owing to the rigidity of the abdominal muscles, but when the attack passes off the tenderness generally becomes localised to the gall-bladder itself. In some early cases the gall-bladder is found to be enlarged owing to distension with clear fluid, especially if the stone is impacted in the cystic duct. Very commonly it gradually contracts on the stone or stones within it, probably after temporary dilatation, so that in long-standing cases it is rarely palpable. Even if a gall-stone passes into the common bile-duct, the gall-bladder does not often become enlarged; thus a large gall-bladder in a case of chronic jaundice generally indicates chronic pancreatitis or a growth of the head of the pancreas or of the common bile-duct.

Pure cholesterol gall-stones are never visible with the X-Rays, but when much lime salts are present, especially in thin patients, they often throw a characteristic shadow. The shadow must be distinguished from that produced by a renal calculus, a calcified tuberculous focus in a kidney, a calcified tuberculous gland or a calcareous deposit in a costal cartilage. This can now be easily done by means of cholecystography. This method also makes it possible to photograph transparent stones, as they are seen as pale areas surrounded by the dark shadow formed by the dye filling the rest of the gall-bladder. Failure to produce a cholecystogram on two successive occasions, especially in the presence of a good shadow of the liver, which proves that the dye has been absorbed from the intestines, indicates that the cystic duct is obstructed, probably by an impacted stone, that the lumen of the gall-bladder is entirely occupied by stones, or that its mucous membrane is so damaged that it is incapable of absorbing water and so producing the concentration of the bile necessary for the production of a shadow.

Complications.—Cholecystitis is always present before gall-stones develop, except with the rare solitary sterile cholesterol stone. If the mouth of the cystic duct becomes obstructed suppuration or gangrenous cholecystitis may develop (p. 702). In some cases inflammation may spread up the hepatic ducts or down the common bile-duct; in the latter case the pancreatic ducts may become infected and chronic pancreatitis develops. In rare cases glycosuria or actual diabetes follows. Cancer of the gall-bladder or bile-ducts occurs in about 4 per cent. of people over 40 with multiple-faceted gall-stones compared with 0.4 per cent. of those with no gall-stones and with solitary cholesterol stones. The former are secondary to chronic cholecystitis, the latter to some metabolic disorder: the carcinoma is, therefore, presumably a result of the chronic cholecystitis, together perhaps with a

direct chemical or mechanical carcinogenic action of the stones on the inflamed mucous membrane.

Treatment.—During an attack of biliary colic the pain should be controlled by the injection of morphine with atropine.

The early recognition and thorough treatment of cholecystitis can be regarded as a true method of prophylaxis of gall-stones.

Treatment of cholecystitis may also result in the solution or washing away of cholesterol deposited on the walls of the gall-bladder and of minute agglomerations of crystals—the basis of what might later become gall-stones. Moreover, even when definite stones are present it may cause the accompanying indigestion, the so-called gall-bladder dyspepsia, which is really due to the cholecystitis, to disappear. However, if the symptoms point definitely to the presence of gall-stones, an operation should be advised, unless on account of obesity or renal or cardiac complications the patient is a bad subject for operation. Myocardial disease is not, however, a contra-indication, as the cardiac condition frequently improves after cholecystectomy and patients with impaired hearts often stand the operation remarkably well. Fat patients should be strictly dieted for 2 or 3 months in order to bring their weight down before operation. Except in urgent cases a short preliminary course of treatment with hexamine (p. 705) is always advisable before operating, and the liability to complications or the recurrence of symptoms is greatly reduced by the regular use of magnesium sulphate to prevent stagnation of bile after the operation. Wherever feasible cholecystectomy should be performed in preference to cholecystostomy.

BILIARY COLIC WITHOUT GALL-STONES

It occasionally happens, especially in otherwise healthy young adults of both sexes, that typical attacks of slight or severe biliary colic, generally unaccompanied by jaundice, occur in the absence of gall-stones. During an attack and for a short time afterwards the gall-bladder is found to be tender. The bile obtained through a duodenal tube from the gall-bladder is normal in every way. Cholecystography occasionally reveals some abnormality in the cystic duct in the form of acute angulation with or without dilatation of the proximal segment, and pressure upon the visualised gall-bladder, especially in a direction from its vertex towards its neck, causes pain; the gall-bladder is sometimes unusually large.

On abdominal exploration the gall-bladder looks healthy, but it may be tightly distended. Careful examination may show some abnormality in the anatomy of the cystic duct or an accessory cystic artery may be present, which results in kinking when the gall-bladder is in certain positions. The condition is analogous to Dietl's renal crises. Cholecystectomy is generally followed by permanent cure, though neither macroscopical nor microscopical examination shows any abnormality in its walls or contents.

When no anatomical abnormality is discovered, the condition is probably identical with that which gives rise to attacks of biliary colic after cholecystectomy for gall-stones or cholecystitis, and which leads to the assumption that a stone has been left in the common bile-duct, though at operation no stone or other cause of organic obstruction is discovered. The attacks are,

I believe, caused by a disturbance of the neuro-muscular mechanism of the biliary ducts and the sphincter of the common bile-duct—achalasia of Oddi's sphincter. When the gall-bladder has been removed, the common bile-duct often dilates to form a reservoir, which to some extent takes its place; this can only be due to the resistance offered by the unrelaxed Oddi's sphincter to the flow of bile, corresponding with the dilatation of the oesophagus following achalasia of the cardia. It may take a long time for the neuro-muscular mechanism of the common duct and its sphincter to adapt itself to the conditions present after cholecystectomy, and during this period attacks of pain may result from temporary obstruction by the closed sphincter when the dilated common duct is attempting to empty itself.

Diagnosis.—This condition can be diagnosed if, with typical attacks of biliary colic associated with definite tenderness of the gall-bladder, cholecystography shows that no stone is present and the bile obtained from the gall-bladder is normal. Between attacks the tenderness over the gall-bladder gradually disappears, whereas in cholecystitis it rarely goes completely. When several attacks of colic occur after cholecystectomy has been performed for gall-stones by a competent surgeon, crises of this kind are the most probable cause.

Treatment.—Regular contraction of the gall-bladder and ducts and relaxation of Oddi's sphincter can be promoted by giving Epsom salts with belladonna when fasting in the morning and olive oil half an hour before meals. When this fails, the gall-bladder may have to be removed, as the obstruction is then probably due to an anatomical and not a neuro-muscular derangement. Post-operative cases can generally be relieved by Epsom salts and olive oil. They would probably occur much less frequently if this treatment was given to all patients for some months after cholecystectomy.

CARCINOMA OF THE GALL-BLADDER

Carcinoma of the gall-bladder is a rare disease, which constituted only 0.5 per cent. of the gall-bladders removed at the Mayo Clinic. It is 3 times more common among women than men and few cases occur before the age of 50. Calculi are present in about 75 per cent. of cases.

Symptoms.—In 70 per cent. of cases there is a long history of repeated gall-bladder attacks. This is followed by a short phase of constant pain, accompanied by progressive weakness, anorexia and loss of weight, but no anæmia. The pain is situated in the right hypochondrium and often radiates to the right scapular region. Flatulence, nausea and vomiting are common. A tumour can generally be felt; it may at first be smooth, but later becomes hard and irregular. It is generally not very tender, and there is less muscular rigidity over it than is commonly the case with an inflamed gall-bladder.

After a time secondary deposits lead to symptoms, and in some cases these are most prominent throughout, the primary disease remaining latent. Thus the liver is often large, hard and irregular from the presence of secondary deposits. Jaundice often occurs as a result of extension to the bile-ducts or compression by enlarged glands; it is occasionally remittent or intermittent, when it is generally due to cholangitis or a gall-stone in the common bile-duct.

Ascites is present in about a quarter of the cases as a result of malignant peritonitis or pressure of glands on the portal vein. Extension of the growth to the pylorus or duodenum or to the colon may lead respectively to symptoms of pyloric and intestinal obstruction. The constipation which is generally present tends to be replaced by distressing nocturnal diarrhoea if the pancreas becomes involved. In other cases septic complications, such as suppurative cholecystitis or cholangitis, or local or general peritonitis, may occur. Death generally supervenes within six months of the development of definite symptoms apart from those due to the preceding cholecystitis or gall-stones.

Diagnosis.—The diagnosis is often exceedingly difficult, but the presence of a hard irregular tumour in the region of the gall-bladder with pain, anorexia and loss of weight in a middle-aged or elderly individual, especially if he has had symptoms pointing to cholecystitis or gall-stones, is suggestive of a growth of the gall-bladder.

Treatment.—It is rarely possible to remove a growth of the gall-bladder owing to the difficulty in making an early diagnosis. The operative mortality is high, and a very large proportion of cases recur within six months. The presence of early carcinoma is occasionally discovered on microscopical examination of a gall-bladder removed on account of chronic cholecystitis with or without gall-stones; permanent recovery may then follow.

CONGENITAL OBLITERATION OF THE BILE-DUCTS

Ætiology.—This rare disease occurs rather more frequently in male than female infants. It is occasionally familial and is not associated with congenital syphilis.

Pathology.—Some unknown toxin probably passes from the mother by the umbilical vein to the foetus. Part of the toxin reaches the liver direct and causes multilobular cirrhosis. The rest passes into the general circulation and reaches the liver by the hepatic artery; it is excreted in the bile and gives rise to unilobular cirrhosis and inflammation of the small and large ducts and gall-bladder, which, being extremely small at birth, become more or less completely obliterated. The disease is thus a combination of portal and biliary cirrhosis with obstruction of the ducts.

Symptoms.—Jaundice is generally present at birth, but may not appear for two or more weeks. The meconium is normal, but the stools are free from bile from the first, and the urine is deeply bile-stained. The liver and spleen are large and hard. The infant is often remarkably well till the terminal stage, when purpura and hæmorrhages from the mucous membranes and umbilicus are common and convulsions may occur.

Diagnosis.—Deep jaundice, with a large liver and spleen and hæmorrhages, without any early evidence of infection in a new-born infant is generally due to this disease.

Prognosis.—Life may last from a few days to as much as 11 months.

Treatment.—No treatment is of any value.

CARCINOMA OF THE BILE-DUCTS

Ætiology.—The incidence of carcinoma of the bile-ducts is about half that of carcinoma of the gall-bladder. It is associated with gall-stones in about 50 per cent. of cases. Males are affected slightly more often than females.

Pathology.—The growth arises most frequently in the ampulla of Vater, when a papillomatous projection into the duodenum develops. The common hepatic duct and the common duct are next most affected; a growth of either of the two hepatic ducts is very rare. Primary growths of the cystic duct can rarely be recognised, as at the time of death they are likely to have spread either to the gall-bladder or to the junction with the hepatic duct.

Symptoms.—The first symptom is generally jaundice, which develops gradually, and is often intermittent; though the *faeces* are clay-coloured they generally contain a little stercobilin. Apart from loss of weight and strength, the symptoms are those of obstructive jaundice, but pain may be felt in the epigastrium or right hypochondrium, and attacks of colic may occur. In a case of mine the symptoms simulated those of duodenal ulcer and there was no jaundice, as ulceration of the growth had destroyed Oddi's sphincter. The condition was recognised with the X-Rays by the presence of a filling defect on the inner aspect of the descending part of the duodenum associated with a diverticulum representing the ampulla of Vater. Occult blood is always present in the stools, and the patient may become extremely anæmic. The gall-bladder and less frequently the liver is enlarged. The primary tumour is never palpable. Ascites may occur as a result of secondary malignant peritonitis or of pressure of glands on the portal vein. The course of the disease is sometimes remarkably slow; in one case of mine the patient lived for over two years after the first attack of jaundice.

The diagnosis from carcinoma of the pancreas, chronic pancreatitis and a stone in the common bile-duct is discussed on p. 719.

Treatment.—Life may be rendered more bearable as well as considerably prolonged by cholecystenterostomy if the obstruction is in the common bile-duct, or by external drainage of a dilated duct if it is at or above the junction of the cystic and hepatic ducts. Owing to the almost insuperable technical difficulties of the operation, it is very rarely possible to excise a growth of the ampulla of Vater.

ARTHUR F. HURST.

DISEASES OF THE PANCREAS

THE INVESTIGATION OF DISEASES OF THE PANCREAS

The pancreas produces an external secretion—pancreatic juice, and an internal secretion—insulin. The two functions are entirely independent, and in the diseases affecting the former, which are alone considered in this section, glycosuria due to deficient insulin is rarely present and never severe.

The pancreatic juice reaches the duodenum by the large duct of Wirsung

and the small duct of Santorini. The duct of Wirsung runs by the side of the common bile-duct for a short distance and then joins it to form the ampulla of Vater, a small cavity in the wall of the descending part of the duodenum, which opens in the biliary papilla, the end of the duct being kept closed by the tonic action of Oddi's sphincter. The duct of Santorini discharges through a small papilla a short distance nearer the pylorus, but in 30 per cent. of normal individuals it is not patent or is too small to perform the functions of the duct of Wirsung if the latter is obstructed. The common bile-duct is completely surrounded by the head of the pancreas in 62 per cent. of bodies; in the remainder it lies in a more or less deep groove in the gland. It is clear from these anatomical facts that deficient pancreatic digestion may occur owing to failure of the pancreatic juice to reach the intestine either as a result of diffuse disease of the pancreas, which inhibits the activity or actually destroys the secreting cells, or as a result of obstruction caused by a gall-stone in, or a growth of, the ampulla of Vater occurring in one of the 30 per cent. of people with an incompetent duct of Santorini. The effect on digestion will obviously be the same in each case. It is further clear that in 62 per cent. of cases of chronic inflammation or cancer of the head of the pancreas jaundice will result; but, if the duct of Santorini is incompetent, jaundice accompanied by deficient pancreatic digestion may be equally well due to obstruction of the ampulla of Vater without disease of the pancreas.

The Stools in Deficient Pancreatic Digestion.—The stools are bulky and pale owing to excess of fat, the proportion of which in the dried faeces may be increased to 60 to 80 per cent. from the normal of 15 to 25 per cent. The pallor is still more marked in the presence of jaundice, as stercobilin is then absent or reduced in quantity. The fat is present chiefly in its neutral form, whereas normally only about 10 per cent. is unsplit; in rare cases it separates as oil, which solidifies on cooling. Microscopically oil droplets are seen, together with crystals of fatty acids and soaps, which are formed by bacterial decomposition of the undigested fat, but the proportion of neutral fat to fatty acids and soaps remains high, in contrast with the excess of the latter and small proportion of the former in chylous diarrhoea due to deficient absorption (pp. 615, 616). Fragments of undigested meat can sometimes be recognised with the naked eye, especially if the presence of excess of fat is prevented by giving a fat-free diet; striated muscle fibres are always recognisable with the microscope, but owing to the activity of the diastatic ferment of the succus entericus there is no excess of undigested starch. In severe diarrhoea associated with rapid passage through the small intestines, the stools may contain some excess of undigested fat, meat and starch in the absence of pancreatic disease.

The irritating products of bacterial decomposition of undigested fat and meat may give rise to diarrhoea; in such cases excess of mucus is often present.

Pancreatic Ferments in the Duodenal Contents, Faeces and Urine.—The duodenum normally contains trypsinogen, which is converted into active trypsin by the enterokinase of the intestinal juice, amylopsin (diastase) and steapsin (lipase). Under the conditions already described, in which no pancreatic juice reaches the intestine, the ferments cannot be isolated from the duodenal contents obtained through an Einhorn tube; but it is impossible

to recognise with certainty a simple reduction in the quantity present, owing to the great variations which normally occur and the technical difficulties in the quantitative estimation of the ferments. The same is true with regard to their presence in the stools, but a rough estimate of the quantity of pancreatic juice secreted can be made by measuring the tryptic activity of the fæces. On the other hand, the quantity of diastase present in the urine is fairly constant and not difficult to estimate. In destructive disease of the pancreas it is not reduced, as the ferment is apparently formed in the liver and simply excreted by the pancreatic juice. Consequently in acute pancreatic necrosis the diastase index is increased from the normal of between 6 and 30 units to 200 or more, and in many cases of subacute necrosis and of growth of the pancreas, especially during exacerbations which manifest themselves by increase in pain, it is increased to a less extent, a unit being the number of cubic centimetres of 0.1 per cent. starch solution digested by 1 c.c. of urine. The index is low in renal disease owing to deficiency in the excreting power of the kidney.

Carbohydrate Metabolism.—Although the secretion of insulin is rarely much affected in the diseases of the pancreas considered in this section, a rise in the blood sugar with or without slight glycosuria is sometimes observed, and the glucose tolerance test may show some deficiency in carbohydrate metabolism; in doubtful cases this is a strong point in favour of pancreatic disease.

ACUTE NECROSIS OF THE PANCREAS

Synonym.—Acute Hæmorrhagic Pancreatitis.

Ætiology.—The pressure under which bile is secreted is about 30 mm. to 100 mm. higher than the maximal pressure attained in Wirsung's duct after a meal, when pancreatic secretion is most active. Bile is not, however, forced into the pancreas, as the normal tone of Oddi's sphincter is overcome by a pressure of only 100 mm. But when the mouth of the common bile-duct is obstructed, the bile is forced into Wirsung's duct; the bile salts activate the pancreatic zymogens, auto-digestion by the trypsin, producing necrosis with secondary hæmorrhage of the pancreas, and the steapsin leading to fat necrosis. If the bile is infected, but not otherwise, suppurative necrosis of the pancreas occurs simultaneously; the bacteria also help the bile to activate the ferments.

The obstruction is caused by a gall-stone in 50 per cent. of cases, and in rare instances by a pancreatic calculus or a round worm. When the lumen is free, the obstruction is probably caused by spasm of Oddi's sphincter secondary to acute gastro-duodenitis, which may be caused by acute corrosive poisoning. Necrosis of the pancreas may also follow a direct injury to the pancreas producing hæmorrhage.

Very rarely infection reaches the pancreas by way of the blood stream in pyæmia and infective endocarditis, and abscesses may result from retro-grade thrombosis in suppurative pylephlebitis. Acute pancreatitis has been observed in influenza, typhoid fever and small-pox. It is a rare complication of mumps, but suppurative necrosis never occurs.

Pathology.—Necrosis, hæmorrhages and suppuration are found in varying proportions in the pancreas. Opaque white areas of fat necrosis are found in the fat of the pancreas, the retroperitoneal tissue, omentum and mesentery, and also occasionally in that of more distant parts, such as the pericardium, to which the pancreatic lipase has been conveyed by lymphatics. Bacteria, especially *B. coli* and streptococci, can generally be isolated from the inflamed gland and often from the gall-bladder. The peritoneal cavity often contains bloodstained fluid, especially in the lesser sac; in the later stages this fluid is infected and suppurative peritonitis may be present.

Symptoms.—Without any warning a sudden very violent pain is felt in the epigastrium. It continues without intermission, but paroxysms of still more severe pain occur from time to time. Severe pain across the back is often present. After a short time vomiting begins and is repeated at frequent intervals; the gastric contents are first ejected, and after a time the vomit contains bile. Flatus may be passed, but the bowels are not opened, and no sounds indicating gastro-intestinal activity can be heard on auscultation. The abdomen soon becomes distended; it is very tender on palpation, but the muscles are often not correspondingly rigid. The tenderness and rigidity begin in the epigastrium, but before long become general. In rare cases the enlarged pancreas can be felt, but the rigidity of the abdomen generally makes this impossible. Slight jaundice is occasionally present as a result of pressure of the swollen pancreas on the common bile-duct. The patient soon becomes collapsed, with a weak and rapid pulse and slight cyanosis; he appears more severely ill in the first few hours than is generally the case in acute peritonitis. The temperature is not greatly raised and may be sub-normal, and leucocytosis is generally absent. Dyspnoea is occasionally observed. Glycosuria is rare, probably because death occurs too rapidly, as the diabetes produced in animals by the removal of the pancreas often does not develop until some days have elapsed. The diastase index of the urine is always raised above 100 and generally above 200.

Diagnosis.—The possibility of acute pancreatitis should be considered in all cases of acute symptoms in the upper part of the abdomen in adults, especially if the patient is an elderly obese, alcoholic individual, who has previously suffered from symptoms which might have been due to gall-stones or gastro-duodenal catarrh. A careful history often reveals the fact that the patient has previously had one or more similar, but much slighter attacks, probably due to acute but localised necrosis from which complete recovery took place. The symptoms may closely resemble those due to perforation of a gastric or duodenal ulcer, but in the latter there is generally a history pointing to the presence of an ulcer before the onset of acute symptoms; vomiting is continuous in pancreatitis, but occurs only at the onset or not at all in perforation, and the hepatic dullness does not alter in pancreatitis, but often disappears owing to the escape of gas through a perforated ulcer; and the abdominal muscles are generally less rigid in pancreatitis than in perforation. In other cases acute intestinal obstruction is simulated, but flatus generally continues to be passed, the abdomen is less distended, and intestinal sounds disappear at once instead of being unusually loud at first. A rise in the diastase index to 100 or more is conclusive evidence in favour of acute pancreatitis. At the operation the discovery of fat necrosis at once makes the diagnosis clear.

The occurrence of sudden severe epigastric pain, incessant vomiting, epigastric tenderness, and occasionally an elongated tumour in the situation of the pancreas on the third to the eleventh day in a case of mumps, is probably due to acute pancreatitis; glycosuria and jaundice are extremely rare, but diabetes has been recorded as a sequel.

Prognosis.—The most acute cases are always rapidly fatal unless an operation is performed. Some cases run a subacute course, especially if one or more localised abscesses form; the illness may then continue for a week or lead to chronic pancreatitis. Only one fatal case of pancreatitis due to mumps has been recorded, complete recovery generally occurring within a week without any operation being required.

Treatment.—An operation should at once be performed in all cases of acute pancreatic necrosis, except in those complicating mumps, the pancreas being drained at the site of greatest damage. If gall-stones or cholecystitis are present the gall-bladder should also be drained. The earlier the operation is performed, the greater is the prospect of recovery, but permanent deficiency of pancreatic secretion may follow.

SUBACUTE NECROSIS OF THE PANCREAS

Pathology and Symptoms.—Necrosis may occur in very small areas of the pancreas as well as in the generalised form just described. This condition is most frequently associated with gall-stones and with penetrating gastric or duodenal ulcer. It gives rise to recurrent attacks of mid- or left-sided epigastric pain, which tends to radiate round the left costal margin or to bore through to the muscles immediately to the left of the lower dorsal spine, when it may simulate renal colic. It may spread upwards to the left shoulder and downwards to the left iliac fossa and even to the left thigh and leg. The attacks generally occur two or three hours after food, when the functional activity of the pancreas is at its height. The pain may be associated with deep tenderness, but there is little or no rigidity, and the abdomen is often much distended. The patient may be perfectly well in the intervals between attacks. As in acute pancreatic necrosis, the attacks are often associated with cyanosis and a weak, though not specially rapid, pulse.

The stools are generally normal, and there is no constant glycosuria, but there may be temporary hyperglycæmia and glycosuria during the attacks.

Diagnosis.—Attacks of left-sided pain occurring in cholelithiasis and after cholecystectomy are generally due to subacute pancreatic necrosis, which may also account for pain boring through to the back in gastric and duodenal ulcer, though I have seen very severe pain of this kind in which the ulcer was found at operation to be free from adhesions and the pancreas healthy. The sudden violent abdominal pain, with tenderness, rigidity and leucocytosis, which may be noted in an attack of diabetic coma, is probably of similar origin.

Treatment.—The recurrence of attacks may be prevented if a diet is given which affords as complete rest as possible to the pancreas. The patient should be starved for 3 days and then given carbohydrates alone

for 3 days. After that a more liberal diet is allowed, but fats and meat should be given very sparingly in spite of the fact that the stools show no evidence of pancreatic insufficiency.

In severe attacks the question of operation requires consideration: gall-stones, if present, should be removed and the gall-bladder drained but not excised.

CHRONIC PANCREATITIS

Ætiology and Pathology.—Chronic pancreatitis is generally due to infection spreading up Wirsung's duct. This is most likely to occur if the pancreatic secretion stagnates owing to obstruction of the duct, especially in an individual in whom the duct of Santorini is insufficiently developed to drain the gland. A small gall-stone impacted in the ampulla of Vater obstructs the mouth of Wirsung's duct and generally leads to chronic pancreatitis; if impacted in the terminal part of the common bile-duct, this complication may also occur, especially in an individual in whom the duct is completely surrounded by the head of the pancreas.

In rare cases the duct is obstructed by a pancreatic calculus, but this is probably itself a result of catarrh of the pancreatic ducts. Cancer of the head of the pancreas, and obstruction of the mouth of the common bile-duct by cancer of the ampulla of Vater or of the duodenum, are generally complicated by chronic pancreatitis, as the flow of pancreatic juice is obstructed.

When no obvious obstruction is found to account for chronic pancreatitis, the disease may be due to a gall-stone which has been passed, but the infection can also ascend from the duodenum, or descend from the upper biliary passages, as non-calculous cholecystitis is sometimes present. The cases which occur in alcoholic individuals are probably secondary to gastro-duodenal catarrh, and a typhoidal infection of the bile passages probably accounts for the occurrence of chronic pancreatitis as a sequel of typhoid fever. When a chronic gastric or duodenal ulcer erodes the pancreas, the neighbouring part of the gland becomes chronically inflamed.

In chronic pancreatitis the inflammation and the fibrosis to which it gives rise are mainly interlobular, coarse bands of connective tissue, often visible to the naked eye, separating the lobules of the gland from each other. The head of the pancreas is generally most affected; it is hard and somewhat enlarged.

Symptoms.—In chronic pancreatitis the normal functions of the pancreas must be more or less disturbed, but in the majority of cases it is entirely latent, as it is rare for the inflammation to be sufficiently severe and widespread to interfere seriously with pancreatic digestion. It is generally found accidentally during an operation for gall-stones, or at autopsy if the primary disease proves fatal. In an individual in whom the pancreas completely surrounds the common bile-duct jaundice is likely to develop. It is generally the only symptom, and chronic painless obstructive jaundice, developing insidiously without any of the initial symptoms characteristic of catarrhal jaundice, is generally due to chronic pancreatitis. The gall-bladder is dilated unless chronic cholecystitis has made relaxation of the walls impossible, but it is generally difficult to recognise by palpation, and the liver

is often enlarged and abnormally hard, but not tender. In the rare cases in which pancreatic indigestion is present, the stools contain excess of fat and undigested meat (p. 612) and diarrhoea may result; the deficient digestion causes very gradual emaciation with increasing weakness. In exceptional cases diarrhoea is severe, emaciation is rapid and extreme, and there is complete anorexia.

Diabetes rarely results from chronic pancreatitis, but it may occur in very chronic cases if the inflammation spreads into the lobules and invades the islands of Langerhans.

Though chronic pancreatitis itself does not give rise to pain, severe attacks of colic are occasionally observed as a result of attacks of subacute necrosis even in the absence of gall-stones; the pain tends to radiate along the left costal margin, and to bore through to the muscles immediately to the left of the lower dorsal spine and to the angle of the scapula. Left-sided pain of this kind in gall-bladder disease should suggest the possibility that the pancreas is involved, and in chronic gastric and duodenal ulcer that penetration into the pancreas has occurred.

Diagnosis.—It is rarely possible to determine with certainty whether chronic pancreatitis is present as a complication of gall-stones or of the other conditions with which it may be associated. If hyperglycæmia with or without glycosuria develops in such a case, it is extremely probable that the pancreas is becoming affected. The changes in the fæces, which result from the absence of pancreatic digestion, do not prove that the pancreas is affected in a case of chronic jaundice, as in individuals in whom the duct of Santorini does not function obstruction of the ampulla of Vater may prevent the pancreatic juice as well as the bile from reaching the duodenum, although the pancreas is healthy.

The possibility of chronic pancreatitis should be considered in all cases of chronic jaundice in which the cause is doubtful. If the jaundice is preceded by symptoms of acute febrile gastro-duodenitis, catarrhal jaundice is the most likely diagnosis. Attacks of pain, even in the absence of a characteristic history, make the presence of gall-stones probable. In the absence of such attacks, especially if the gall-bladder be enlarged, either chronic pancreatitis or a growth is probably present. A growth is much more commonly associated with chronic pain, and emaciation and weakness develop more rapidly than with chronic pancreatitis. It is often impossible, however, even at an operation, to distinguish between a growth of the head of the pancreas and chronic pancreatitis; only when a patient recovers completely and permanently is it possible to be certain that the condition was inflammatory.

Prognosis.—The prognosis depends upon that of the primary condition in secondary cases, and the presence of chronic pancreatitis does not alter the outlook in operations for gall-stones. In cases of apparently primary pancreatitis complete recovery has taken place after an exploratory operation in which nothing was done. Chronic pancreatitis only causes death in the presence of complications. In one case death followed peritonitis secondary to rupture of the distended gall-bladder the day before an operation was to be performed. In another the patient, who had suffered from painless jaundice for six months, refused operation, and death resulted from gastrointestinal hæmorrhage, the exact source of which could not be found at

the autopsy ; it was apparently secondary to subacute necrosis of the liver, which had resulted from the long-continued biliary stasis.

Treatment.—It is only necessary to consider the treatment of those cases which appear to be primary, as when the pancreatitis is secondary no treatment beyond what is necessary for the primary disease is required. If the jaundice does not abate within three months, or a shorter period if the patient rapidly loses weight and strength or the lævulose test shows that the functional efficiency of the liver is becoming impaired, an operation should be performed. A cholecystenterostomy will cure the jaundice, remove one source of irritation of the pancreas by draining the infected bile, and prevent the development of secondary inflammation and necrosis in the liver. The operation has no ill effects, and should therefore be performed in spite of the fact that some cases have recovered when nothing was done at the operation.

SYPHILIS OF THE PANCREAS

The pancreas is affected in 20 per cent. of cases of congenital syphilis in the newborn ; in most cases the liver is simultaneously affected, and somewhat less frequently the spleen, bones, lungs and other organs. The gland is enlarged and hard owing to proliferation of the interlobular connective tissue ; the gland-cells atrophy, but the islands of Langerhans escape.

Syphilis in adults occasionally gives rise to chronic pancreatitis, and much less frequently to gummata of the pancreas.

Symptoms.—The symptoms are those of chronic pancreatitis or carcinoma of the pancreas. The tumour may be palpable, and it may lead to obstruction at the pylorus or duodeno-jejunal flexure with persistent vomiting. The occurrence of diabetes in a syphilitic patient should suggest that the pancreas may be affected. The Wassermann reaction should always be tested in cases of suspected chronic pancreatitis and carcinoma of the pancreas, whether the diagnosis is made clinically or at an operation, and in diabetes, and anti-syphilitic treatment instituted if it is positive.

PANCREATIC CALCULI

Ætiology.—Pancreatic calculi are extremely rare. The majority of cases have occurred in middle-aged men.

Pathology.—Between five and ten calculi are generally found, but in rare cases one only or as many as 300 may be present. They are white, yellow or brown, and vary in size from mere sand to smooth or irregularly shaped masses, an inch or more in length. Although pancreatic juice contains no calcium carbonate, this is the chief constituent of the calculi, which consequently throw much more definite shadows than gall-stones with the X-Rays. If they reach the ampulla of Vater, a deposit of cholesterol and bile-pigment may form over them, causing them to become externally indistinguishable from gall-stones. Calculi never form in a healthy pancreas ; they result from infection of the ducts and stagnation of the secretion. The ducts behind the calculi are dilated and show catarrh of their walls, and

chronic pancreatitis is often present, but suppuration is very rare. The condition may be associated with gall-stones.

Symptoms.—In most cases the calculi have only been discovered after death. They may cause attacks of epigastric pain very similar to biliary colic, but the pain radiates along the left costal margin and may extend to the angle of the left scapula, and vomiting is generally absent. Fragments of calculi may be passed after an attack. Obstruction of the main pancreatic duct may lead to the changes in the stools and urine described on p. 714. A stone may cause jaundice by pressing on the common bile-duct or by passing into the ampulla of Vater.

Treatment.—If the condition is diagnosed the calculi should be removed by operation.

PANCREATIC CYSTS

Ætiology.—Simple obstruction of the pancreatic duct leads to atrophy of the secreting tubules and not to the formation of cysts. Only when chronic pancreatitis is also present retention cysts may develop; most are secondary to gall-stones, a few to pancreatic stones or a tumour.

Hydatid cysts may develop in the pancreas, and a few cases of congenital cystic disease, generally associated with cystic disease of the kidneys, have been described.

A large proportion of so-called pancreatic cysts are really pseudo-pancreatic cysts, being collections of fluid in the lesser sac of the peritoneum, the foramen of Winslow having been occluded by peritonitis. About a quarter of these cases follow an injury to the pancreas, which causes the escape of blood and pancreatic juice into the lesser sac with secondary peritonitis. In the remaining cases serous fluid collects slowly as a result of local peritonitis secondary to pancreatitis, the condition being analogous to a pleural effusion following pneumonia.

Pathology.—A single large pancreatic cyst may contain as much as 14 pints of fluid. Multiple cysts of various sizes, often quite small, may occur. Fragments of gland substance may be found in their walls. The cyst is sometimes in direct communication with the pancreatic duct, but in other cases the latter is obliterated. It is often adherent to the surrounding parts. It may rupture into the lesser sac of the peritoneum, the general peritoneal cavity or the stomach.

The contents of true pancreatic cysts are generally turbid and dark reddish-brown or yellow in colour. The fluid is alkaline, slightly viscid and albuminous, and may contain altered blood; microscopically degenerated epithelial cells, leucocytes, and occasionally crystals of cholesterol and rarely of leucin and tyrosin are found. The pancreatic ferments are often absent, especially in old cysts.

Symptoms.—There are often no symptoms when the tumour is accidentally discovered. In other cases symptoms due to the disease which gave rise to the cyst may precede its discovery. When the cyst has reached a considerable size there may still be no symptoms, but sometimes attacks of epigastric pain, which may radiate to the left shoulder, occur; they are sometimes accompanied by vomiting, wasting and jaundice. Glycosuria is very rare, but true diabetes has developed in a few cases.

The tumour is generally in the centre of the upper part of the abdomen, but it often extends farther to the left than the right. It does not move on deep respiration and is only very slightly movable in each direction. As it grows it extends farther down and may finally appear to fill the entire abdomen. It is smooth, rounded and elastic; a thrill is often produced on striking it. A large cyst may push the diaphragm upwards and impede respiration. It may compress the stomach and intestines and cause indigestion and constipation; very rarely it obstructs the common bile-duct and causes jaundice or obstructs the inferior vena cava and causes cedema of the legs.

Its relation to the stomach and colon can be readily determined by means of the X-Rays after a barium meal and enema. It is first behind the stomach, but as it enlarges it generally reaches the anterior abdominal wall between the stomach above and the transverse colon below. Less frequently it comes forward above the stomach or below the transverse colon between the leaves of the mesocolon. It generally grows very slowly, but sudden enlargement may result from hæmorrhage into it.

Diagnosis.—There ought to be no difficulty in diagnosing a pancreatic cyst from ascites and from a hydronephrosis, enlarged gall-bladder, ovarian cyst or distended bladder. It is impossible to distinguish a true pancreatic cyst from a pseudo-pancreatic cyst clinically; even at an operation the distinction may be impossible. Mesenteric cysts are generally more movable than pancreatic cysts.

Treatment.—The cyst should be emptied and drained by operation. It is never wise to attempt to remove it owing to the dense adhesions which often fix it to its surroundings. The immediate results of operation are very satisfactory, but a recurrence is not uncommon.

CARCINOMA OF THE PANCREAS

Ætiology.—Primary carcinoma of the pancreas occurs about three times as frequently as primary carcinoma of the liver, but whereas secondary carcinoma of the liver is very common, secondary carcinoma of the pancreas has only one-third of the frequency of the primary disease. In secondary carcinoma the pancreas is generally invaded by direct spread of the growth from the stomach; less frequently a small secondary deposit is found when the primary disease is situated in some distant situation.

Cancer of the pancreas occurs three times as frequently in males as in females.

Pathology.—The head of the pancreas is involved in 75 per cent. of cases, in some of which the disease probably originates in the pancreatic ducts. Cancer of the head of the pancreas obstructs the duct, which becomes dilated and occasionally forms retention cysts. The stasis of the pancreatic secretion frequently leads to chronic pancreatitis and very rarely a pancreatic calculus. Secondary deposits are often found in the neighbouring lymphatic glands, the liver and peritoneum, and less often in more distant organs.

Symptoms.—When the head of the pancreas is involved, jaundice is generally present owing to pressure on the common bile-duct, but the

latter may escape if it is not embedded in the gland. The jaundice increases until it is very intense, bile being then completely absent from the faeces. The gall-bladder is almost always distended and is generally palpable; the liver is also generally large and hard. When the growth is confined to the body or tail of the pancreas there is no jaundice unless the duct is compressed by a secondary deposit, and neither the gall-bladder nor liver is enlarged. There are no distinctive symptoms, and a correct diagnosis is rarely made before death. Severe pain is present in most cases. It is generally left-sided and often radiates through to the back. Occasionally attacks of colic occur in the same region, especially at the onset of jaundice. Wasting is rapid in almost all cases, and the patient becomes progressively weaker. If the head of the pancreas is involved, the stools may have the characteristic described on page 714, and diarrhoea is likely to occur.

The tumour is not often palpable, as it is deep-seated and likely to be hidden by the enlarged liver and the ascites, which is present in a third of the cases as a result of malignant peritonitis or pressure on the portal vein. In thin patients it is sometimes felt just above the umbilicus; it is hard, fixed and sometimes slightly tender.

Diagnosis.—Chronic jaundice due to carcinoma of the head of the pancreas must be diagnosed from chronic pancreatitis, a gall-stone in the ampulla of Vater, and carcinoma of the ampulla of Vater. Pain is often absent in chronic pancreatitis and the general health is very little impaired, whereas in carcinoma pain radiating to the left side of the back or in the back alone is often present, and there is a steady deterioration in health. A gall-stone rarely reaches the ampulla of Vater without a preceding attack of colic, whereas jaundice is generally the first symptom in carcinoma of the head of the pancreas; the jaundice in the former is often incomplete and intermittent instead of complete and permanent, pyrexia is common, and rigors may occur owing to infection of the bile passages. In carcinoma of the ampulla of Vater the jaundice, which is accompanied as in carcinoma of the pancreas by dilatation of the gall-bladder, is less complete and more intermittent than might be expected; it can sometimes be recognised with the X-Rays by the characteristic filling defect it produces in the duodenum, and it always leads to the presence of occult blood in the stools.

In the absence of jaundice the possibility of a growth of the tail of the pancreas should be considered in a patient whose general condition suggests that he is suffering from cancer, but in whom no evidence of disease can be found in the organs most commonly affected; the possibility is converted to a probability if he complains of severe pain boring through to the left side of the back.

Prognosis.—Death generally occurs within six months of the onset of symptoms and is rarely delayed beyond a year.

Treatment.—If there is the smallest doubt about the diagnosis in a case of chronic jaundice, an exploratory laparotomy should be advised. If a growth of the pancreas is found, a cholecystenterostomy should be performed in order to relieve the jaundice and thus save the patient from one of the most distressing of his symptoms. Moreover, in numerous instances permanent recovery has followed this operation when performed for a supposed growth of the pancreas, the surgeon having mistaken chronic

pancreatitis for a growth. No operation can be of any use in the absence of jaundice, even in the rare cases in which a correct diagnosis is made.

ARTHUR F. HURST.

VISCEROPTOSIS

Synonyms.—Glénard's Disease ; Enteroptosis.

Ætiology and Pathology.—Visceroptosis is most frequently due to a fall in intra-abdominal pressure, caused by weakness of the abdominal and pelvic muscles, the normal tone of which maintains the viscera in position. The tone of the abdominal muscles is often impaired by the stretching which they undergo during pregnancy. After parturition the sudden diminution in the volume of the abdominal contents is so great that a considerable fall in intra-abdominal pressure occurs, as the stretched muscles are at first very lax. If the patient remains in bed for a sufficient period, they gradually regain their tone, and the separated recti come together again, but otherwise they become permanently weakened. Weakness of the abdominal muscles is common among people who take too little exercise. Atrophy and degeneration of the abdominal muscles are also produced by malnutrition in such conditions as rickets and prolonged fevers.

The pelvic floor consists of a muscular diaphragm, which is formed by the levator ani, together with other less important muscles. These may be damaged in difficult labour, and a slighter degree of weakness is frequently present in addition to that of the abdominal muscles in individuals who lead a sedentary life.

When the intra-abdominal pressure is abnormally low, the viscera drop directly gravity comes into play, but at first they regain their normal position as soon as the individual lies down. At a later stage, when the daily descent of the viscera has continued for a considerable time, the displacement persists in the horizontal position.

The degree of ptosis of the different organs depends upon their weight and upon the length and elasticity of their peritoneal attachments, which, in the absence of their natural support, act as true ligaments.

True visceroptosis must be distinguished from the "hyposthenic habitus," a constitutional condition common in women, but comparatively rare in men, which is characterised by a long narrow chest and a small epigastric angle. In this the viscera are congenitally lower than in the average individual, owing to the relatively small capacity of the upper part of the abdominal cavity.

Symptoms.—Most of the symptoms of visceroptosis occur only when the erect position is assumed. They consequently disappear on lying down and are absent at night. They are temporarily relieved when the lower part of the abdomen is compressed by means of the hand, and in women they frequently show a steady improvement as pregnancy advances owing to the rise in intra-abdominal pressure and the support given to the viscera by the growing uterus. They are often worse in the later part of the day than in the morning owing to the progressive relaxation of the abdominal muscles resulting from fatigue.

The symptoms have been ascribed in turn to the kidneys, stomach, intestines and uterus, according to which happened to be the special object of study. It is certain, however, that the general effects are commonly of much more importance than those due to ptosis of individual organs.

GASTROPTOSIS.—Gastroptosis is uncommon, and even when present it is rarely the cause of symptoms. The normal stomach varies greatly in length. In the erect position it swings between the cesophagus, where it passes through the diaphragm, and the junction between the movable duodenal bulb and the descending retro-peritoneal portion of the duodenum. In a stomach of average length the umbilicus (or inter-iliac line) is about half-way between the lesser and greater curvatures. The greater curvature of the short hypersthenic stomach does not reach the umbilicus. On the other hand, in the long stomach, which is particularly common in individuals with a hyposthenic habitus, the lesser as well as the greater curvature is below the umbilicus, and the latter may reach the true pelvis. This condition has generally been called gastroptosis, but, as it is congenital and the stomach has never occupied

FIG. 19.—Gastroptosis without duodenal ptosis, resulting in kink at junction between bulb and descending part of duodenum: (a) standing, (b) lying.

From "Gastric and Duodenal Ulcer" (Hurst and Stewart). (Oxf. Med. Pub., 1929.)

a higher position, the name is quite inappropriate. Moreover, the long stomach is just as competent as a short one or one of average length.

When the abdominal muscles become weak, a long stomach is likely to be more affected than one of ordinary length, and a short one does not drop at all. But the gastroptosis caused in this way does not lead to kinking of the pylorus, as the pyloric end of the stomach together with the first part of the duodenum is surrounded by peritoneum and is freely movable. It may, however, give rise to a kink where the first part of the duodenum joins the second or descending part, as the latter is situated behind the peritoneum and is less mobile (Fig. 19). Discomfort may then occur, which begins during the meal and reaches its greatest intensity as soon as all the food has been taken. It depends more upon the quantity than the quality of the food, milk producing just as much disturbance as an equal weight of solid food. In most cases, however, the duodenum drops with the stomach, and a considerable degree of gastroptosis may be present with little or no gastric disturbance (Fig. 20). It is thus always necessary to note the position of the duodenum as well as that of the stomach during an X-Ray examination: if

the upper extremity of the duodenum is not at least an inch above the umbilicus, duodenal ptosis is present.

After having found the position of the stomach and duodenum in the erect and horizontal positions, it must next be determined whether the stomach evacuates its contents in a normal manner. If the duodenum drops with the stomach, the passage of food out of the stomach and through the duodenum is generally normal in rate. This is also sometimes the case even if the duodenum has not dropped, but more frequently, especially if the ptosis is well marked, it can be seen with the X-Rays that, although the food may pass without difficulty from the stomach into the first part of the duodenum, there is delay in the passage beyond this point.

A second examination should be made 6 hours after the opaque meal, no food having been taken in the interval. The patient should not lie down, but should follow his ordinary occupation. Gastric stasis is present if the stomach still contains food at this second examination. In order to decide whether this is due to the ptosis, a second opaque meal should be given on

FIG. 20.—Gastroptosis with duodenal ptosis: (a) standing, (b) lying.

From "Gastric and Duodenal Ulcer" (Hurst and Stewart). (Oxf. Med. Pub., 1929.)

another day, and the patient should lie on his right side in the interval between the two examinations. If the ptosis is the sole cause of the stasis, the stomach will be empty in 6 hours, and if an intermediate examination is made it will probably be found to be already empty in 3 or 4 hours. If there is no delay in the evacuation of the stomach in the erect position, the indigestion is not due to the gastroptosis.

It is important to observe whether voluntary contraction of the abdominal muscles in the erect posture is sufficient to raise the stomach to its normal position, as if this is the case the prognosis is good, and abdominal exercises and massage together with the temporary use of a support will probably result in a cure. If the stomach cannot be raised to the normal position in this way, the back should be supported by the left hand whilst the lower part of the abdomen is pressed inwards and upwards with the right. In most cases this results in raising the stomach to the normal position, which indicates that an abdominal support is likely to give relief, though it will not by itself cure the condition.

ENTEROPTOSIS (COLOPTOSIS).—Ever since Glénard drew attention to the condition he called "enteroptosis," this has generally been supposed to

produce kinks of the intestines, especially at the flexures of the colon, which give rise to obstruction to the onward passage of fæces, and a pelvic cæcum and a low transverse colon are often referred to as if they are invariably associated with constipation. But I have seen a pelvic cæcum in almost as large a proportion of strong healthy individuals, especially females, with perfect digestion and no constipation as of constipated patients. The colon, like the stomach, varies greatly in length. When the ascending colon is unusually long the cæcum is situated in the pelvis even on lying down. I have rarely seen the transverse colon pass in a straight line from the hepatic to the splenic flexure except in high-caste Indians. The lowest part of the transverse colon of normal people is almost always situated well below the umbilicus in the erect position. When it is longer than the average, as it is in most people with a long stomach, it reaches the true pelvis. Under these conditions neither the pelvic cæcum nor the pelvic transverse colon can be regarded as a result of ptosis.

The position of the colon varies greatly in the course of the day: it is lowest when full and highest when empty (*e.g.* just after defæcation); it is depressed by a full stomach; and a pelvic cæcum and transverse colon are raised out of the pelvis by a full bladder. In normal individuals examined with the X-Rays the hepatic and splenic flexures often appear to be acutely kinked. This is the result of the shadow being cast in a single plane, as the limbs of the flexures belonging to the transverse colon are in front of those of the ascending and descending colon respectively, and the flexures appear to be acute, although they form a wide angle when looked at from the side.

The constipation, which is often associated with visceroptosis, is generally due to the weakness of the abdominal and pelvic muscles and the ptosis of the diaphragm; this interferes with the voluntary part of the act of defæcation. Ptosis of the transverse colon never leads to kinking at the hepatic flexure, as the cæcum and ascending colon drop with it. A true kink is occasionally produced at the splenic flexure, as the phreno-colic ligament is stronger than any other of the intestinal attachments. A dragging pain together with a sense of distension may then be felt in the left hypochondrium.

The characteristic bulging of the lower part of the abdomen and retraction of the epigastrium seen on standing are due mainly to ptosis of the small intestine, but are of no clinical importance.

HEPATOPTOSIS.—When the liver drops it rotates towards the right, or less frequently it falls forward so that its upper surface bulges in the epigastrium. The condition can be recognised by palpation and percussion, the upper border of the hepatic dullness being abnormally low. A palpable liver is thus not necessarily an enlarged one, but may simply be displaced. It gives rise to no special symptoms beyond a vague discomfort in the right hypochondrium which may radiate towards the shoulder; it is increased by jumping, walking and coughing, and disappears on lying down.

A *dropped spleen* can be distinguished from a large spleen by the fact that it can be manipulated into its normal position, where it is no longer palpable; it generally gives rise to no symptoms, but in very rare instances great pain is produced by twisting of its pedicle.

For *nephroptosis*, see p. 1316.

When the pelvic floor is weak, it allows the *pelvic viscera* to drop, and

retroflexion of the uterus generally occurs simultaneously ; it may also result in actual prolapse of the uterus and rectum.

Downward displacement of the *diaphragm* results in dyspnœa, as, being constantly in the position of extreme inspiration, it is no longer possible for its normal respiratory excursions to occur. This is particularly noticeable in patients with weak hearts, whose abdominal muscles have been stretched by an accumulation of ascitic fluid which has since been absorbed or tapped. The downward displacement of the diaphragm is accompanied by a similar displacement of the heart, which gives rise to no special symptoms.

Under normal conditions the abdominal wall and pelvic floor are the only support of the viscera ; the peritoneal folds help to maintain them in position, but they do not support their weight. If, as a result of weakness of the muscles of the abdominal wall and of the pelvic floor, the viscera drop when the individual is erect, a pull is exerted on the peritoneal folds, which become true suspensory ligaments. Their sensory nerves are constantly stimulated, the patient often complaining of vague abdominal discomfort, which is generally described as a weight or pressure or as being of a dragging nature ; it is relieved by lying down and by pressure upon the lower part of the abdomen. The discomfort is most marked in neurasthenic individuals owing to the irritability of their nervous system ; if the nervous system is healthy it may be completely absent. It is increased by exercise and physical fatigue and to a less extent by mental fatigue. The chronic pain aggravates the nervous depression, a vicious circle being thus produced, but neurasthenia is never a result of visceroptosis alone.

Visceroptosis leads to an alteration in the centre of gravity of the body. In order to maintain the upright position certain muscles of the spine which are ordinarily little used are brought into action ; this is a frequent cause of chronic backache.

The maintenance of the circulation when the erect position is assumed depends to a considerable extent upon the tonic contraction of the abdominal muscles. When this is deficient, as it is in visceroptosis, the abdominal veins dilate and the pulse becomes abnormally accelerated on standing ; giddiness and syncope may also occur.

Treatment.—Much can be done to prevent visceroptosis in women by proper management of the puerperium. The patient should remain in bed for the first 12 or 14 days after parturition, in order that the most active period of involution of the pelvic organs should be completed before the uterine supports are subjected to strain. But when much bruising has occurred, especially in the case of primiparæ, or when the mother is much debilitated by frequent child-bearing, this period should be extended to 3 or 4 weeks. During the whole of this time exercises for the abdominal and perineal muscles should be regularly practised under expert supervision. Most of the time during the first few days after getting up should be spent on a couch, and a return to full physical activity should only be permitted after 6 weeks.

The first indication in the treatment of visceroptosis is to raise the intra-abdominal pressure. In order to do this the condition of the abdominal and pelvic muscles must be improved. Exercise out of doors and special remedial exercises are of great value. It is essential to prevent the over-stretching of the muscles, which occurs whenever the erect position is assumed, as it is

impossible for them to regain their normal postural tone so long as they have to bear the weight of the viscera for the greater part of the day. In many cases, therefore, a support is required for a time, but it should be discarded as soon as the abdominal muscles have regained their normal postural tone. An abdominal support should fit closely to the symphysis pubis and Poupart's ligaments below; it should not extend above beyond the umbilicus. It should be so made that it presses the abdominal contents upwards, backwards and inwards. In mild cases of visceroptosis in women all that is necessary is a special straight-fronted corset, which does not constrict the waist, but supports the lower part of the abdomen. In most cases, however, a light support, hinged in the middle line and fixed in position by steel springs, which pass over the hips to end in pads applied to the sacrum, is required. The abdominal support should always be put on when the patient is lying down with the pelvis raised so that the organs are held in proper position, and it should be worn all day. Not infrequently the X-Rays show that the stomach and colon drop on standing almost or quite as far when the support is worn as without it. This is particularly likely to occur in cases in which an organ falls into the true pelvis, as the support does not then reach low enough, and in thin patients upon whom it is impossible to exert sufficient pressure. Such a patient, however, often derives benefit from wearing a support, although it does not hold the colon or stomach up. It acts by increasing the intra-abdominal pressure, many of the symptoms ascribed to kinks being really the result of the low intra-abdominal pressure interfering with the circulation and with the proper performance of defæcation.

When visceroptosis is due in part to weakness of the pelvic floor, this may require treatment by pessaries and local operations, which have the object of restoring the injured parts to a more normal condition, but an exercise for the levator ani muscles is often of great value in such cases. The patient is instructed to perform the movement she would make were she attempting to overcome an urgent desire to defæcate. The exercise should be repeated about thirty times twice a day while in the recumbent position. I have often seen a tendency to prolapse of the rectum and of the uterus overcome in this way, the associated dyschezia being cured at the same time.

Gastroptosis only requires treatment in the exceptional cases in which it has led to definite gastric stasis. In slight cases the patient should lie down after meals, but in severe cases, in which there is much emaciation or the abdominal muscles are greatly atrophied, it is best for her to remain in bed for some weeks, as by this means the intra-abdominal pressure is reduced to a minimum, and all tension is removed from the abdominal and pelvic muscles. The foot of the bed should be raised as high as possible, as this helps the organs to return to their proper position, which is often maintained after the patient gets up again, especially if she gains weight during the rest. She should lie on her right side during and for an hour after meals. She should only sit up to open her bowels and to wash when her stomach is empty before breakfast, and even then a pad should be bandaged over the lower part of the abdomen so that the stomach should not drop. After the complete rest is over she should continue to wear an abdominal support and should at first lie for an hour on her right side after meals. Small meals should be given at frequent intervals, and food should be chosen which contains a maximum of nourishment in a minimum of bulk. Upward massage is

useful, especially if the stomach or colon is low in the horizontal as well as in the vertical position: it is most effective if the masseuse gives her first treatment under the X-Ray screen, so that she can see what manipulations are required to bring the stomach and colon back to their normal position.

In no circumstances should any operation be performed for raising dropped viscera. I have never seen the slightest benefit follow, and the mental condition of many of the patients makes surgical interference of any kind most undesirable.

GASTRO-INTESTINAL ALLERGY

When paroxysmal attacks of abdominal pain, often associated with vomiting or diarrhoea or both, are not obviously the result of biliary or renal colic, the possibility of abdominal allergic attacks should be considered. The pain may occur in any part of the abdomen, and its situation generally varies in different attacks. The onset is sudden, and the attack terminates abruptly after a period lasting for a few minutes to 24 or 48 hours. The patient has no abdominal symptoms of any kind in the intervals between the attacks, which may occur almost every day or not more than once or twice a year. Nothing abnormal is found on examining the abdomen between the attacks, and during the attacks there is little or no rigidity and generally little or no tenderness. The pain may be extremely severe and only partly relieved by morphine. It is often associated with vomiting and, when the pain is in the lower part of the abdomen, watery diarrhoea with or without mucus, but without blood, is generally present.

The patient often gives a family history of asthma, hay fever, skin diseases or migraine, and he is often himself a sufferer from one or other of these conditions. The abdominal attacks generally occur, however, during periods of complete freedom from other allergic manifestations, so that the frequent presence of slight eosinophilia is an important help in diagnosis. Still more characteristic is the complete relief obtained by injecting 2 to 5 minims of adrenaline (1 in 1000), as this drug has no effect on any other form of abdominal pain.

Cutaneous reactions may show that the patient is sensitive to certain articles of food, especially wheat, milk and eggs in the case of children, and pork or other flesh food and spinach in adults, but the absence of such reactions does not exclude an allergic origin of the symptoms, nor does their presence prove with certainty that the articles consumed must be excluded from the diet. Gastro-intestinal allergy occurs at all ages, but is probably most common in infants and children.

Treatment.—The patient should avoid any articles of food which he has found give rise to attacks, and also any which give a positive cutaneous reaction. If attacks continue to be frequent, the effect of $\frac{1}{2}$ grain of ephedrine hydrochloride three times a day before meals should be tried. Nocturnal or early morning attacks may be prevented by taking 1 to 2 grains of luminal on going to bed. The patient should learn to give himself adrenaline, and at the first sign of an attack he should inject the smallest dose which experience shows

prevents an attack: generally 1 to 3 minims are sufficient. The injection can be repeated at intervals if the attack does not at once completely disappear.

ARTHUR F. HURST.

DISEASES OF THE PERITONEUM

ACUTE PERITONITIS

Definition.—Peritonitis is the disease which results from infection of the peritoneum with bacteria. Owing to the large area of the peritoneum and its great powers of absorption the results are very severe, and because of its intimate relationship to the alimentary canal the risk of such an infection occurring is considerable.

Ætiology.—Infection may reach the peritoneum (1) from without; (2) by the blood stream; and (3) from the contained organs.

1. Infection from without is possible in the case of wounds, but is of infrequent occurrence. In most instances severe abdominal wounds injure the contained viscera also, and the consequent peritonitis is usually the result of this.

2. Infection by the blood stream is an occasional though uncommon mode of infection. In streptococcal and staphylococcal septicæmia peritonitis may occur as a terminal event; it frequently gives rise to so few symptoms, however, that its existence is unrecognised during life. When pneumococcal peritonitis complicates pneumococcal lesions elsewhere the infection is undoubtedly blood borne.

3. Infection from contained or neighbouring organs is by far the commonest cause of peritonitis. The majority of cases depend more or less directly on the passage of bacteria from within the alimentary canal owing to changes in its walls. The appendix is the most frequent seat of the primary condition. When there is no actual breach of continuity in the organ, bacteria escaping through its damaged walls generally lead to the formation of peritoneal adhesions and possibly to a local abscess. When, however, the infection is particularly virulent or the patient's resistance unusually poor, a sufficient local reaction does not take place, and spreading diffuse peritonitis results. This is commoner in children than adults, and may occasionally occur, even when the local reaction has been good, through manipulation or ill-judged surgery separating the adhesions and allowing the infection to spread. Diverticulitis and acute cholecystitis are occasional aduses of this type of acute peritonitis, but more usually result in local adhesive changes. Peritonitis complicating typhoid fever in the absence of perforation, and pneumococcal peritonitis when associated with pneumococcal enteritis, have a similar origin.

In intestinal obstruction and strangulated hernia the changes which occur in the bowel wall speedily permit the passage of organisms through it to the peritoneum. This takes place first in the neighbourhood of the obstruction, but as paralysis and distension spread along the bowel, organisms can make their way through, and consequently most cases of this type are

widely generalised. The infection, however, is gradual, and the reactive forces of the peritoneum have time to respond. By far the commonest organism in these cases is the *B. coli communis*, usually preceded by or accompanied by the *Staphylococcus epidermidis albus*.

Perforation of a hollow viscus into the peritoneal cavity is responsible for some of the most virulent and widespread cases of peritonitis; the lower the perforation in the bowel, the more virulent the resulting infection will be. The appendix is the commonest source, gangrene or a perforating ulcer leading to a sudden peritoneal infection before any gradual passage of organisms has had time to produce a local peritoneal reaction. Perforating ulcers of the stomach and duodenum come next in order of frequency; less common causes are perforating ulcers of the ileum, the most important of which is the typhoid ulcer, rupture of the gall-bladder, bile-ducts or ureters, and perforating wounds of any of the hollow organs, or leakage from surgical anastomoses. Abscesses of the liver, appendix, gall-bladder or Fallopian tubes occasionally burst into the general peritoneal cavity. Infection of the peritoneum may also result by direct spread from neighbouring parts. This type of case is particularly common in women, spread taking place either directly through the Fallopian tubes, or by lymphatic permeation of the uterine walls. Peritonitis is a very rare sequel to infections of the lung and pleura, although the reverse is far from unusual. In the infant an infection of the thrombosed umbilical vein may lead to peritonitis by direct spread.

Symptoms.—As acute peritonitis is almost invariably a secondary condition, its symptoms and course are subject to very considerable variations, depending not only on the nature of the primary lesion from which it arises and on the nature and virulence of the infecting organism, but also on the general condition of the patient.

1. *Acute generalised peritonitis.*—This is usually associated with the perforation of a hollow organ or the sudden bursting of an abscess into the peritoneum, and owes its chief characters to the fact that in such cases the peritoneum is suddenly flooded with infection without any preliminary preparation. The patient may have been free from any symptoms of ill-health, and is suddenly seized with very acute abdominal pain, accompanied sometimes by a sensation of something having given way. The pain may at first be localised in position, and thus help in the diagnosis of the actual lesion; but it speedily spreads to the whole abdomen, and is followed almost at once by a feeling of syncope or collapse. Within a few minutes the patient becomes cold and pale; his features are pinched and betray the most intense anxiety; beads of sweat stand out upon the skin, and the pulse may be almost imperceptible. He complains of nausea, but does not often vomit, and his respirations are shallow and quickened. In a short time a certain amount of improvement takes place; the pulse, though rapid, is of better volume, and the pain may take on an intermittent colicky character. The abdomen is absolutely rigid, and is usually retracted, though it may be distended; it is very tender on pressure. The liver dullness is usually absent; but this is only important if an abdominal examination made at the onset of the attack revealed a normal area of dullness. These symptoms are caused by the perforation or other primary cause and the resultant flooding of the peritoneum with infective material. Occasionally they may be sufficiently severe to lead to death by themselves; but more usually they gradually

merge into the symptoms of the consequent acute peritonitis itself. The latter are reactive in nature, and are due to Nature's attempts to limit the process.

The patient becomes extremely restless, this being one of the most characteristic and distressing features of nearly all forms of peritonitis. Owing to the loss of fluid by sweating, vomiting and exudation, the subcutaneous tissues become shrunk and give the patient the so-called "*facies Hippocratica*." The tongue is dry and furred, and the teeth become covered with *sordes*. The pulse increases in rate and becomes thready and later running in character, and the temperature, which at first may be subnormal, rises. The abdomen is of a uniformly board-like rigidity and extremely tender. It is held immovable, respiration being entirely thoracic, and the patient lies with his knees drawn up to relieve the abdominal tension. There is usually absolute constipation, and the intestinal sounds are absent. Gradually the paralytic intestine becomes dilated and the abdomen distended. Vomiting is early and frequent. The vomited matter is usually only small in quantity; it speedily becomes exceedingly foul, though it is rarely *fecal*, and the breath is extremely offensive. The urine is scanty and may contain traces of albumin, and its passage may produce a paroxysm of pain. It usually contains a large amount of indican.

Throughout the whole course of the disease the outstanding feature is the pain. This may at first be intermittent and colicky; but as the peritonitis develops it becomes constant and agonising, being increased by the smallest movement. In spite of this the restlessness persists, the patient being unable to resist the desire to move his limbs. The pain and restlessness, with the persistent vomiting, the intense thirst, which is hardly relieved by drinking, combine to make the patient's misery extreme. The pulse increases in rapidity until it can scarcely be counted, the extremities become cold, the eyes grow more sunken, and the features more pinched. As death approaches, the skin takes on a cyanotic hue; the persistent restlessness, the increasing voicelessness, and the remorselessly unimpaired consciousness bring death as a merciful release, even though the pain may be somewhat relieved towards the end.

The foregoing description applies to an acute fulminant case of peritonitis, running its course to death in from 24 to 48 hours; its outstanding features are a condition of profound shock and *toxæmia*, giving a measure of the high grade of peritoneal absorption. In the aged, and in patients with *tuberculosis* or *Bright's disease*, the symptoms may be very atypical; pain may be but little marked, and vomiting and tenderness may be absent, while the bowels may act freely throughout. The striking restlessness, the condition of the tongue, the pulse and the ultimate meteorism will, however, usually indicate the true nature of the condition.

2. *Acute spreading peritonitis.*—This variety differs from the preceding in that the peritoneum is not suddenly flooded with infective material, but is prepared for infection by the more or less gradual spread of the condition. It accompanies many cases of *appendicitis*, and is a sequel of intestinal obstruction if unrelieved for a sufficiently long period. The peritoneal reaction is intense, and the coils of intestine become glued together with a sticky exudate, while pockets of pus form between them. If surgical interference is not undertaken these cases may progress for weeks. The pain

is at first localised to the region of origin ; but as the infection spreads it extends until it may become generalised over the whole abdomen. It is, however, never so intense as in the preceding variety, and may be distinctly spasmodic in character. The general abdominal symptoms are also less severe, the tenderness, rigidity, meteorism and constipation being of varying grade. The aspect of the patient betokens a profound septic infection, the tongue is furred and dry, the pulse rapid, and the temperature of the hectic type. Rigors and sweats are not uncommon, and if left alone the case may terminate with fatal septicæmia, suppurative pylephlebitis, or in rare cases the pus may accumulate and burst either externally in the region of the umbilicus or into one of the hollow viscera.

3. *Pneumococcal peritonitis*.—This presents fairly characteristic features, which in many cases enable the nature of the infection to be correctly diagnosed from the clinical picture alone. It is far more frequent in children than in adults, and in girls than boys in the proportion of nearly 7 to 3. It occurs in a diffuse and an encysted form, depending probably on the resistance of the patient. In many cases there exists a definite pneumococcal enteritis, the organisms penetrating the wall of the bowel and so infecting the peritoneum. The predominance of the disease in girls is probably due to the female genitals being a source of infection, as the pneumococcus has been cultivated from the vagina in some instances. In the majority of cases, however, the peritonitis is part of a pneumococcal septicæmia ; thus, when it is secondary to pneumococcal disease of the middle ear, local pneumococcal abscesses or pneumococcal arthritis, the blood stream appears to be the source of infection, and it probably is so also in those cases which follow pneumonia or empyema, since the physics of the upper abdomen renders a direct spread through the diaphragm unlikely.

There is a striking resemblance between the symptoms of most forms of pneumococcal infection, a resemblance which strongly supports the view of their origin in a septicæmia. The onset is usually sudden, often accompanied by a chill and a high temperature, the pain is violent and persistent, and the prostration severe. The patient has the characteristic flush, the respiratory rate is raised, and the accessory muscles of respiration are called into play. Vomiting is frequent, and tenderness and rigidity are marked ; but in place of the usual absolute constipation there is frequently profuse diarrhœa, which, associated with the other symptoms of acute peritonitis, is often almost diagnostic. In the diffuse form, unless operation is undertaken, death takes place early ; but if the patient lives long enough there may be a sudden fall of temperature about the seventh day, as in pneumococcal pneumonia.

The encysted and more common variety of pneumococcal peritonitis is less severe, and shows a remarkable tendency for pus to collect in the lower abdomen. There is the same acute onset as in the diffuse variety ; but the patient then appears to improve for a few days. Later, however, he gets gradually worse, the abdomen becomes distended, the diarrhœa changes to obstinate constipation, and an abscess forms in the lower abdomen and finally bursts at the umbilicus. The exudate in these cases is a greenish, odourless pus, which is sufficiently characteristic to enable the infection to be diagnosed when it is discovered at operation.

4. *Gonococcal peritonitis*.—Gonococcal peritonitis is rare ; it occurs both as an acute diffuse affection of the peritoneum and as a localised pelvic inflammation. It is commoner in females than in males, owing to the ready channel for infection through the Fallopian tubes, and when it occurs in males it is usually secondary to epididymitis. The infection is generally a mixed one, the more fragile gonococcus being readily overgrown, and some cases of unexplained peritonitis, which on culture show only *B. coli*, are possibly gonococcal in origin. The symptoms do not differ in the diffuse cases from those of other forms of acute peritonitis, although the primary focus usually gives rise to symptoms. The prognosis is, however, good, and the majority of cases, even those presenting severe symptoms, recover without operation.

5. *Streptococcal peritonitis*.—Peritonitis due to the *Streptococcus pyogenes longus* is occasionally secondary to lesions of the alimentary canal ; but much more frequently it is a sequel of puerperal infections. It occurs commonly after a first delivery, and is frequently associated with retained products. Infection takes place along the lymphatics of the damaged uterus or through the Fallopian tubes, and may be localised in the pelvis ; but it often gives rise to generalised peritonitis. The symptoms are characteristic, and are associated with evidence of a marked septicæmia. The abdominal walls, being already greatly stretched, do not show the usual rigidity, and extreme distension occurs rapidly. Diarrhœa is commoner than constipation, and a high temperature with rigors is usual. The uterine discharges are offensive, the milk secretion is suppressed, and the cases frequently progress to death within the first week. This type of infection is more fulminant than any other, except certain cases of perforative peritonitis.

Diagnosis.—The diagnosis of acute peritonitis is not usually difficult, except in cases where the severity of the casual condition is so great that it masks the peritoneal response, or where the peritonitis occurs in a patient already so severely ill that no response is possible. It is often extremely difficult to make a correct diagnosis of the lesion to which the peritonitis is secondary, and in many cases this is only possible after laparotomy. The most valuable signs of acute peritonitis are the severe pain and tenderness, the rigid abdomen, the small, rapid, and thready pulse, the dry tongue, the restlessness, vomiting, and constipation, and the absence of sounds of gurgling on auscultation. Any of these symptoms may, however, be absent, and a diagnosis must be based on their occurrence in combination. In post-operative cases there is sometimes a remarkable absence of both pain and rigidity, and the all-important early recognition of the condition in these patients is often one of much difficulty.

Peritonitis is most likely to be mistaken for lead colic or acute intestinal obstruction. From the former it can be distinguished by the fact that the abdomen in peritonitis is usually extremely tender, while in colic pressure often, though not invariably, relieves the pain : in colic a blue line is present, and the red corpuscles show punctate basophilia, the pain is intermittent, and there is usually no vomiting and less extreme rigidity. From acute intestinal obstruction the diagnosis is often far more difficult, particularly since the two conditions frequently coexist. In the early stages of obstruction, before peritonitis has developed, the intermittent nature of the pain, the absence of great tenderness or rigidity, the copious nature of the vomit

and the evidence of increased peristalsis from inspection or auscultation should help to distinguish the two conditions.

In acute pancreatitis the pain is more definitely hypogastric, the patient is usually over middle age, and collapse is extreme. The menstrual history, the typical pallor, and the results of vaginal examination usually serve to indicate a ruptured tubal pregnancy, and in other acutely painful abdominal conditions the localised nature of the pain and the absence of any extreme general tenderness help to distinguish the condition from peritonitis.

The gastric crises of tabes are seldom likely to be a source of error; but the comparative absence of severe symptoms in tabetics, the subjects of peritonitis, is very apt to lead to a mistaken diagnosis.

Basal pneumonia and diaphragmatic pleurisy may lead to acute abdominal symptoms. The temperature and pulse, the raised respiration rate, and a routine examination of the thorax in all cases should prevent a mistake being made.

Prognosis.—The prognosis of acute peritonitis is always grave, even with early surgical treatment. Without operation no case of acute perforative peritonitis can be expected to recover; such exceptions as have been recorded must be regarded as medical curiosities. Under these conditions death generally takes place within 48 hours, though it may be delayed a week or even longer when the perforation is high in the bowel and the latter is empty at the time.

In diffuse spreading peritonitis and streptococcal puerperal infections death is almost as invariable, unless operation is undertaken; but the process is less rapid, and a small proportion of cases undoubtedly recover without surgical aid. These cases occasionally merge into a form of chronic fibropurulent peritonitis, characterised by the progressive formation of collections of pus between neighbouring viscera, and by repeated outbursts of symptoms as other parts of the peritoneum become successively involved. This condition usually terminates in fatal septicæmia, with infections in the pleura, pericardium or endocardium. The prognosis in pneumococcal cases is considerably better, as, even without operation, a fair proportion recover, either with or without the formation of a hypogastric purulent collection, which may discharge at the umbilicus. In the rare gonococcal cases recovery is the rule, and the fatal cases recorded have almost invariably followed operation.

In forming a prognosis the chief importance must be placed on the degree of toxæmia and the severity of the intestinal paralysis, and to a less extent on the degree of meteorism and the frequency of the vomiting. Spontaneous bowel actions or their induction by enemata make the peritonitis relatively more favourable.

The rate of rise of the pulse and its ratio to the temperature are also of importance; cases with a subnormal temperature throughout are almost always rapidly fatal.

Treatment.—The principles that must underlie the successful treatment of acute peritonitis are, firstly, the removal or limitation of the process to which the peritonitis is secondary by a thorough and speedy exploration of the abdomen, followed by closure of a perforation, removal of an appendix, or such other measures as the pathology present may indicate; secondly, drainage and relief of tension in the peritoneal cavity; thirdly, the encouragement of

the normal peritoneal response and the least possible damage to its protective agencies; and, fourthly, the combating of the shock and toxæmia.

By the adoption of the Fowler position, in which the patient is propped up in bed in a sitting position, not only is infective material removed from the dangerous diaphragmatic area and brought into contact with the much more highly resistant pelvic peritoneum, but at the same time the diaphragm is relieved from the pressure of the dilated stomach and intestines.

A further important adjunct to surgical treatment is the subcutaneous injection of large quantities of saline solution. This raises the blood pressure and redresses the fluid depletion which has taken place, and, being excreted by the peritoneum, it reverses to a certain extent the lymphatic circulation, and consequently largely prevents the absorption of toxic material as well as dilutes that already present. Anti-gas gangrene serum is often of value in combating the toxæmia arising from the paralysed bowel.

Until a definite diagnosis has been made and operation advised and agreed to, the administration of opium in any form is definitely contra-indicated. It masks the symptoms, and by bringing to the patient and his advisers a false sense of security may lead to a fatal delay in undertaking the operation. When, however, a diagnosis has been made, and operation is agreed to, morphine is beneficial in reducing both the mental and physical symptoms, while the necessary preparations are being made. The aperient method of treatment was introduced with the object of preventing the onset of intestinal paralysis and in order to eliminate as far as possible toxic material by the bowel. The great objection to it, however, is the fact that in practically no case is the peritoneal infection absolutely general, at any rate at first, and consequently there is a danger of spreading infection by means of increased peristalsis, while it is doubtful to what extent purgation prevents intestinal paralysis if the toxæmia is considerable. The exact opposite line of treatment has been the one adopted more and more of recent years, morphine being given deliberately and in doses sufficient to affect the respiration rate with the object of diminishing the activity of peristalsis, as well as of combating the shock, pain and restlessness, which help so largely to exhaust the patient's powers of resistance. It is very doubtful whether it ever prevents the response of the bowels to enemata in cases in which they would otherwise respond. If vomiting is a prominent symptom, lavage of the stomach is of value. It should, if possible, always be done before operation, as post-anæsthetic vomiting of faecal material is a fruitful cause of fatal broncho-pneumonia.

In pneumococcal cases there is not quite the same urgency for operation, and it is sometimes justifiable to wait for a time in the hope of localisation. In gonococcal peritonitis, if a diagnosis can be made, conservative treatment should be followed; but if there is doubt, as there often must be, of the nature of the infection, or if the patient shows any increase of symptoms, laparotomy is the only safe course to follow.

E. G. SLESINGER.

CHRONIC PERITONITIS

(a) LOCALISED CHRONIC PERITONITIS ; PERITONEAL ADHESIONS

Ætiology and Pathology.—Inflammation of the appendix and operations on the appendix, especially if followed by drainage, lead to the formation of adhesions in the neighbourhood. Adhesions near the hepatic flexure are often due to cholecystitis, and less commonly to a subacute or acute perforation of a duodenal or gastric ulcer. Pelvic peritonitis, which is a common sequel of disease of the female genital organs, often involves the pelvic colon, and occasionally the cæcum and appendix, and tuberculous peritonitis is an important cause of local and generalised intestinal adhesions. Dense adhesions are also caused by diverticulitis, especially of the iliac and pelvic colon, and occasionally by ulcerative colitis. Adhesions to the scar are very common after abdominal operations, especially if active inflammation was present at the time of the laparotomy. In many cases bands are found which differ in structure and anatomical relations from these inflammatory adhesions ; they are most probably of congenital origin, but perhaps they persist and become thickened and altered as a result of mechanical factors. These bands are often supposed to form kinks and obstruct the lumen of the bowel. Thus those in connection with the end of the ileum are said to cause kinking (" Lane's ileal kink ") and ileal stasis. There is, however, no evidence that any connection exists between ileal kinks and ileal stasis, as structural abnormalities found at operation are no proof that functional abnormalities coexist, and the improvement which follows simple division of bands in connection with the end of the ileum is so inconstant that the operation is now rarely performed. The obstruction offered by an ileal kink is hardly ever as great as that offered by the normal ileo-cæcal sphincter three inches farther on.

In exceptional cases localised adhesions give rise to partial obstruction, particularly in the more distal parts of the colon, the contents of which are solid, and therefore more easily held back by a slight narrowing in the intestinal lumen. In the more proximal parts, such as the hepatic flexure, adhesions can only cause any considerable degree of stasis if they give rise, as they occasionally do, to a local spasm of the circular muscle-fibres of the intestine. Spasmodic strictures of this sort are intermittent, and the obstruction which they cause may be more or less completely overcome by anti-spasmodic drugs.

Symptoms.—When the symptoms point to the presence of stasis in one particular part of the bowel, especially if there is local tenderness and pain, which is increased when the intestinal movements are active after meals or during defæcation, the possibility of adhesions should be considered. Their presence is rendered more likely if there is a history of some inflammatory disease, which could have led to their development ; but as adhesions are often present in the absence of such a history, an X-Ray examination is essential. It is, however, important to remember that severe local stasis often occurs without any organic cause, so that radiograms alone can give no aid in diagnosis, palpation under the screen being always necessary in order to determine the mobility of the bowel.

The end of the ileum, as it rises from the pelvis to join the cæcum, bends

in various directions ; as the shadow on the screen is in one plane only, it is natural that it often appears to form one or more acute angles or kinks ; by palpating the abdomen during the examination, especially after inflation of the colon with air in order to raise the terminal ileum out of the pelvis, it is easy to demonstrate that most of these "kinks" are only apparent. By manipulation of the abdomen during the screen examination it should be possible to separate from each other the limbs of the hepatic flexure and of the splenic flexure ; if this cannot be done it may be presumed that they are bound together by adhesions. Adhesions in connection with the pelvic colon can be recognised by palpation during the administration of an opaque enema. It may prove impossible to pass a sigmoidoscope beyond the pelvic-rectal flexure or some point in the pelvic colon owing to the fixation of the bowel, and attempts to do so cause pain.

Localised intestinal adhesions occasionally give rise to so much congestion of the mucous membrane that occult blood may be constantly present in the stools and a growth of the colon may consequently be simulated.

Treatment.—In many cases considerable relief follows the administration of paraffin to render the stools soft, and the use of belladonna in small doses to prevent the intestinal spasm, which may increase obstruction and lead to colic. A diet which leaves a minimum of indigestible and irritating material but contains sufficient chemical stimulants of intestinal activity should be given. Abdominal massage is also often of use ; and if the abdominal walls are weak, exercises to strengthen them and a suitable support help to prevent dragging upon adhesions.

Operative treatment is very unsatisfactory, as whatever care is taken, there is always a danger of recurrence of the adhesions. Only when they are very localised and lead to definite obstruction at one or more points is it clearly necessary to divide the adhesions and take steps to prevent their recurrence.

(b) DIFFUSE CHRONIC PERITONITIS ; PERIHEPATITIS

Diffuse chronic peritonitis is a condition in which chronic progressive inflammation of the peritoneum occurs independently of tuberculous or malignant disease. The peritoneal covering of the liver is often the part most involved, and the condition has therefore been called perihepatitis ; but, as the ascites is just as much due to inflammation of other parts of the peritoneum, this name is not very appropriate.

Ætiology.—1. Chronic peritonitis may be associated with chronic inflammatory changes in the thorax. Effusion may occur from all the serous membranes (polyorrhomenitis, polyserositis, or Concato's disease) ; this condition is probably in most cases tuberculous. In other cases chronic peritonitis is associated with chronic mediastinitis, adherent pericardium and pleural adhesions ; the disease may apparently start either above or below the diaphragm. The peritoneum covering the liver and spleen is generally most involved.

2. In many cases of chronic peritonitis the kidneys are granular and the arteries thickened, the renal condition being probably primary.

3. Simple chronic peritonitis may be a widespread process of obscure

origin. It may be associated with chronic gastro-enteritis caused by alcoholism. Ascites caused by cirrhosis of the liver, heart failure or renal disease may lead to secondary peritonitis, especially after repeated tapping, probably owing to the irritant action of toxins present in the fluid.

Pathology.—The liver may be covered with a thick, hard and white coating of fibrous tissue, which can be peeled off to expose the smooth peritoneal surface. Perihepatitis is almost always associated with a similar thickening of the capsule of the spleen and with thickening of other parts of the peritoneum. The great omentum may be rolled into a hard cord, and the mesentery may be thick and short so that the intestines are tethered to the posterior wall of the abdominal cavity.

Symptoms.—The only important symptom is ascites. Its onset is generally gradual, but it may be acute. Frequent tapping is required, and the intervals between the performance of paracentesis tend to diminish and may finally be as short as a fortnight, when as much as a pint of fluid may be poured into the peritoneal cavity in a day.

Edema, especially of the feet, is frequent in the late stages; it is generally cardiac or renal in origin, but may also be due to pressure on the inferior vena cava.

Course.—The course of the disease is very slow, death generally occurring from some intercurrent disease. The general health may remain good for a long time.

For the diagnosis and treatment, see Ascites (p. 745).

TUBERCULOUS PERITONITIS

Ætiology.—The peritoneum is involved in 15 per cent. of fatal cases of tuberculosis. Tuberculous peritonitis is rare in infants, and uncommon after 30; the majority of cases occur between the ages of 3 and 20. Boys and girls are equally liable to the disease; it is found much more frequently in women than men at operations, but more frequently in men than in women after death.

Primary tuberculous peritonitis is uncommon in children and rare in adults. It is probably due to infection conveyed by the intestines, which do not themselves become infected, primary tuberculosis of the intestines being rare at all ages. More often, especially in children, the mesenteric glands become tuberculous, generally without any lesion developing in the intestines, and the peritoneum is infected from the glands. In males the primary focus may be the prostate, vesiculæ seminales or testes, and in females the disease frequently begins in the Fallopian tubes; but the latter may also be infected from the peritoneum. Although tuberculous ulcers are found in 75 per cent. of fatal cases of pulmonary tuberculosis, the peritoneum is only affected in 4 per cent. of cases. The peritoneum, the pleura, and occasionally the pericardium, may be involved together in the absence of any other tuberculous focus. Tuberculous peritonitis is found in 9 per cent. of fatal cases of cirrhosis of the liver; this is partly due to the liability to tuberculosis of individuals whose resistance has been lowered by chronic alcoholic poisoning, the localisation in the peritoneum being due to the portal obstruction and chronic intestinal catarrh.

Pathology.—Tuberculous peritonitis may occur in three forms—the ascitic, loculated and obliterative.

1. In the ascitic form, which may be acute, subacute or chronic, miliary tubercles are scattered over the whole peritoneum, which is free or nearly free from adhesions. In chronic cases the tubercles are larger and more fibrotic than in the acute; the peritoneum is thickened and the mesentery is shortened so that the intestines are tethered to the posterior abdominal wall. This form may closely resemble malignant peritonitis.

2. In loculated tuberculous peritonitis the fluid may be clear, the condition being then intermediate between the ascitic and obliterative forms, or it may be turbid or purulent. In the latter case masses of tuberculous material separated from each other by adherent coils of intestine have broken down to form suppurating foci, which may erode the intestine or open at the umbilicus or even into the vagina.

3. Chronic obliterative, adhesive, or fibrous tuberculous peritonitis may occur after absorption of fluid in the ascitic form or may develop primarily. No effusion is present, but universal adhesions obliterate the lumen of the peritoneum, all the viscera being inextricably bound together and to the parietal peritoneum.

In each form of tuberculous peritonitis the mesenteric glands are generally caseous and may break down in the centre; the mediastinal glands may also become tuberculous. The omentum is often rolled into a solid mass, which sometimes contains caseous nodules.

Symptoms.—Tuberculous peritonitis is sometimes completely latent, and may be discovered accidentally during an operation for some independent disease or for a hernia, when the sac may be the only part involved.

The onset of abdominal symptoms is generally preceded by a period of ill-health; the patient loses weight and strength, his appetite is poor, and his temperature may rise slightly at night. After a time he complains of general abdominal discomfort. Nausea and vomiting are rare. Constipation is common, especially in the obliterative form. In other cases diarrhoea may occur, owing to tuberculous ulceration of the intestines, fistulous communications between adjacent coils of intestines, or simple entero-colitis. The stools are sometimes bulky owing to deficient absorption of fat caused by obstruction of the lacteals by caseous mesenteric glands (*vide* p. 616). The spleen and less often the liver may be enlarged. The skin, especially over the abdomen, is dry, inelastic and sometimes so pigmented that Addison's disease is simulated. In chronic cases there is sometimes no pyrexia; more often the temperature is intermittently slightly raised. In acute and suppurative cases the temperature is generally high and irregular, and the pulse is rapid. The urine is often concentrated, especially in ascitic cases, and traces of albumin may be present owing to the pressure on the renal veins caused by the large accumulation of fluid in the abdomen or to the effect of the toxæmia on the renal cells. A moderate degree of anæmia is often present, and leucocytosis develops if suppuration occurs.

In the ascitic form the abdomen gradually becomes distended; at first it is tympanitic, but after a time evidence of the presence of free fluid is obtained, but the quantity is not often very great. Less frequently a large amount of fluid collects with great rapidity; the sudden stretching of the abdominal muscles is likely to cause a considerable amount of pain. Moderate

tenderness of the whole abdomen is generally present. A large accumulation of fluid may compress the inferior vena cava and give rise to oedema of the legs; the diaphragm is pushed upwards and respiration becomes shallow and thoracic. The skin over the abdomen is shiny and the veins are enlarged. The ascitic fluid is generally clear; it contains a large proportion of lymphocytes and often coagulates on standing; less frequently it is turbid or blood-stained. Tubercle bacilli are rarely found in the effusion, although they must be present, as the fluid may produce tuberculosis when injected into guinea-pigs.

In the loculated form with suppuration the abdominal pain is generally greater; attacks of colic are common, especially after exercise. The abdomen is distended and doughy; on percussion, irregular tympanitic and dull areas are found. Large caseous glands and collections of pus between adherent coils of intestines may form palpable masses, which are immobile, tender and dull on percussion. The omentum can often be recognised as a thick cord stretching across the upper part of the abdomen; the transverse colon generally forms a resonant band immediately above it, which helps to distinguish it from the lower edge of an irregularly enlarged liver. The ease with which the masses are felt varies from time to time with the amount of flatulent distension of the intestines. When an abscess is about to point at the umbilicus, the latter becomes indurated, red and tender; a similar condition is occasionally observed in pneumococcal peritonitis and in pelvic peritonitis in women. On rectal and vaginal examination, thickened Fallopian tubes, enlarged glands or collections of pus may be felt.

The signs of obliterative tuberculous peritonitis are ill-defined; the abdomen gives a characteristic rubbery resistance on palpation and is generally somewhat distended. Irregular masses may be felt in it, and the peristaltic waves of the small intestines are often visible, especially in children. This does not necessarily indicate that partial obstruction is present, as it may be simply a result of the abnormal thinness of the abdominal wall.

Symptoms of tuberculous disease of other organs, especially of the lungs, pleura and intestines are often present. Generalised tuberculosis may develop at any time, especially in children; vomiting and constipation, which suggest intestinal obstruction, may be the first symptoms of tuberculous meningitis.

In very rare cases acute peritonitis may develop as a result of rupture of a softened caseous gland or perforation of a tuberculous ulcer.

When a patient recovers from tuberculous peritonitis, the tubercles and adhesions may completely disappear. More frequently localised adhesions remain, and calcified tuberculous mesenteric glands are often found with the X-Rays, at operations and after death. They may give rise to confusion when the abdomen is X-Rayed on account of suspected renal calculi. They do not, however, move with the shadow of the kidney with changes in posture, and in cases of difficulty the diagnosis can always be settled by pyelography. In a very small proportion of cases the bands, which sometimes form from localised adhesions, may cause acute intestinal obstruction, even years after the active disease has disappeared.

Diagnosis.—In the presence of tuberculous disease of the lungs or other organs, abdominal distension, especially if associated with ascites or irregular abdominal masses, generally indicates that tuberculous peritonitis is present.

The discovery of tubercle bacilli in the sputum, and their much less common discovery in the fæces or vaginal discharge, is very strong confirmatory evidence. Ascites in children, and in females with symptoms pointing to tuberculous salpingitis, is generally due to tuberculous peritonitis.

Acute cases may at first closely simulate pneumococcal peritonitis or even appendicitis; but in non-tuberculous inflammatory exudates of the peritoneum most of the cells are polymorphonuclear leucocytes instead of lymphocytes. Ascites due to cirrhosis of the liver in children is almost always mistaken for tuberculous peritonitis; on the other hand, the ascitic form of tuberculous peritonitis in middle-aged alcoholic individuals is likely to be mistaken for ascites due to cirrhosis. When cirrhosis is undoubtedly present, ascites may still be due in part to tuberculous peritonitis; a large proportion of lymphocytes in the fluid is very strong evidence in favour of this, as the ascitic fluid in uncomplicated cirrhosis contains few except endothelial cells. In simple chronic peritonitis there is no fever and little or no pain, and the ascitic fluid contains few if any lymphocytes. The presence of irregular masses, together with fluid in the abdomen, generally indicates tuberculous peritonitis in children; but it is more frequently due to malignant disease in adults, especially in males. The history of the case and any evidence of tuberculous or of malignant disease in other parts of the body help to settle the diagnosis.

Fever, inflammation of the umbilicus, and the presence of lymphocytes in the ascitic fluid point to tuberculosis, whilst nodular infiltration without inflammation of the umbilicus, hard and enlarged glands in the groin or neck, and the presence of large, multinuclear cells or groups of cells in the effusion point to cancer.

A localised collection of fluid may be mistaken for an ovarian cyst, or, if it is in the pelvis, for a hydro- or pyosalpinx, especially if it is associated with tuberculosis of a Fallopian tube; but it forms a less defined tumour than in these conditions.

Prognosis.—Recovery takes place in a large proportion of cases of the ascitic form of tuberculous peritonitis. When localised abscesses develop complete recovery is rare, and when a fæcal fistula forms death almost always follows. Prolonged fever, rapid emaciation and intractable diarrhoea are the most serious symptoms. The prognosis also depends on the severity of any tuberculous disease of the lungs or other organs which may be present. Apparent recovery is sometimes followed by a relapse, generally owing to reinfection from an unhealed primary focus, such as a tuberculous gland, appendix or Fallopian tube.

Treatment.—The patient should be kept in bed so long as the temperature is raised. He should be in the open air all day and night when the weather permits, and if indoors an abundant supply of fresh air is essential. Heliotherapy or artificial sunlight should be employed, but care must be taken to avoid over-exposure. The mercurial ointment, which is often applied on a binder to the abdomen, is probably quite valueless. Diarrhoea should be treated by a non-irritating diet, and in intractable cases by opium preparations. If chylous diarrhoea is present, fat must be excluded from the diet. With this exception, the food should be as abundant and nourishing as possible. Tuberculin has been much employed, but I am not convinced that it is of any use.

The improvement, which often results from allowing the fluid to escape in ascitic cases, is probably caused by flushing the peritoneum with a new exudation of fluid richer in anti-tuberculous substances than that which was allowed to escape. This result can be obtained by simple paracentesis; but an operation has the advantage of making it possible to remove the primary focus, such as a tuberculous gland, a tuberculous appendix with the infected ileo-cæcal glands, or a tuberculous Fallopian tube. All ascitic cases, which do not improve in three months with general treatment, or which get worse instead of better, should therefore be subjected to operation, particularly if there is any evidence pointing to the presence of localised tuberculous disease which might be removed. Operation should never be performed in obliterative peritonitis, in infants less than a year old, or in the presence of extensive tuberculous disease elsewhere. The occurrence of intestinal obstruction is an indication for operation, though it is rarely possible to do anything useful owing to the extensive adhesions present and the danger of tearing the intestines.

PERITONEAL CYSTS

(a) *Hydatids*.—The peritoneum is involved in 1·4 per cent. of cases of hydatid disease. Nearly all cases are secondary, enormous numbers of cysts developing as a result of rupture or leakage of a hydatid of the liver. The cysts grow slowly, and are rarely of sufficient size to give rise to symptoms until two years have elapsed since the primary cysts ruptured.

Hydatid cysts cause a gradual enlargement of the abdomen, which may be diffuse, or separate cysts may be recognised by inspection and by palpation. Symptoms may result from pressure on the stomach, intestines, diaphragm, inferior vena cava, and—in the case of pelvic hydatids—the ureters, bladder and rectum. Single hydatids are generally mistaken for ovarian cysts; but the presence of multiple cystic tumours should suggest the possibility of hydatid disease, which would be confirmed by the presence of eosinophilia, or by the history of a primary cyst in the liver.

(b) *Dermoid cysts* may originate in the mesentery or omentum, especially in women. Ovarian dermoids may also become detached and adhere to any part of the peritoneum, or they may rupture and multiple cysts result from implantation.

(c) *Mesenteric cysts*.—Apart from dermoids and hydatids, cysts may develop in the mesentery or omentum. They may be derived from the dilatation of lymph spaces and be filled with clear, chylous or hæmorrhagic fluid. Mesenteric cysts, lined with endothelium, arise from the distension of shut-in peritoneal pouches with serous fluid. Cysts may project from the free border of the intestine, or grow from its attached border between the layers of the mesentery.

Mesenteric cysts form definite, round, tense tumours, which are generally situated to the right of the middle line and a little below the umbilicus. They may give rise to colic and vomiting and in rare cases to acute intestinal obstruction.

CANCER OF THE PERITONEUM; MALIGNANT PERITONITIS

Ætiology.—Cancer of the peritoneum is almost always secondary. The primary disease is generally in the abdomen, especially the stomach and the ovary, the peritoneum becoming involved by spread along lymphatics or blood vessels, by direct contact, or most commonly by malignant cells being set free and scattered widely over the peritoneum. The disease may also spread from cancer of the breast by the deep lymphatics of the chest and abdominal wall, and by lymphatics from malignant disease of the testis.

Pathology.—Malignant deposits may be minute tubercles, or they may form larger white non-caseating nodules or even very large masses. The parts most generally involved are the omentum, mesentery and pelvis. Chronic fibrotic changes frequently occur, and result in the omentum being rolled up and the mesentery shortened as in tuberculous peritonitis. The diaphragm is often invaded with growth, which spreads to one or both pleuræ. Acute or subacute peritonitis may occur.

Symptoms.—The symptoms are due in part to the primary disease and in part to the secondary malignant peritonitis. As the former is generally situated in the abdomen, it is impossible to distinguish between the symptoms due to the two causes. Malignant peritonitis generally results in ascites; the fluid is clear or turbid, hæmorrhagic, chyloform, or less frequently chylous owing to obstruction and subsequent rupture of lacteals. The umbilicus is often infiltrated with growth, and nodules may be felt along the falciform ligament. Tumours are often felt in the abdomen or on rectal examination; they are sometimes too small to be palpable, and in other cases they can only be felt after the fluid has been removed. The rolled-up omentum can often be recognised as a thick transverse cord above the umbilicus. The malignant masses or peritoneal adhesions may give rise to obstructive symptoms.

Diagnosis.—The development of new abdominal tumours or ascites in a patient who is known to have cancer of the stomach or other organ is conclusive evidence that the peritoneum is involved. When there is no clear evidence pointing to the presence of a primary malignant or tuberculous focus, it may be difficult to distinguish between tuberculous and malignant peritonitis (see p. 743). When ascites is present and no tumour is palpable, cirrhosis, simple chronic peritonitis or portal thrombosis may be simulated; the abdomen should be tapped, when a tumour often becomes palpable if malignant disease is present.

Prognosis and Treatment.—It is rare for the patient to survive for more than six months after the peritoneum becomes involved. Treatment is purely palliative. Considerable relief may follow paracentesis.

ASCITES

Definition.—Ascites is the accumulation of free fluid in the peritoneal cavity.

Ætiology.—Ascites is a constant symptom of simple, tuberculous and malignant chronic peritonitis. It occurs when there is a rise of pressure in

the portal circulation ; it is always present in portal thrombosis and when the portal vein is obstructed by a growth or an aneurysm, and portal obstruction is in part responsible for its presence in cirrhosis of the liver. Ascites is very common in heart failure, in which it is almost always associated with œdema of the feet. It is in part due to the same causes as the œdema, but it is also in part caused by portal congestion, and by obstruction to the lymph flow from the thoracic duct owing to the rise of venous pressure. Lastly, ascites accompanies the dropsy of Bright's disease and severe anæmias.

Symptoms.—The abdomen becomes gradually enlarged, at first in an antero-posterior direction, the costal margin being pushed forward, but at a later stage the bulging occurs in the flanks also. The stretching of the abdominal wall gives rise to a tight sensation, which may amount to actual pain if the fluid collects rapidly. It causes the muscles to atrophy and *lineæ atrophicæ* develop in the skin. The umbilicus becomes everted and may form a thin-walled bladder.

The rise in intra-abdominal pressure caused by the accumulation of ascitic fluid obstructs the inferior vena cava ; œdema of the legs may occur and the obstruction to the renal circulation may cause albumin to appear in the urine, the quantity of which is reduced owing to the loss of water in the ascitic fluid. Compensatory dilatation of other venous channels results : the dilatation of the veins passing between the abdominal wall and those in the falciform ligament is manifested by the development of large and prominent subcutaneous veins around and above the umbilicus ; others pass from the superficial and deep epigastric veins in the middle of the groin towards the costal arch, where they join the superficial epigastric and long thoracic veins. When paracentesis is performed, the dilated veins disappear if they have developed as a result of pressure on the inferior vena cava, but not if obstruction of portal veins is the primary condition.

The diaphragm is pushed up ; its excursions on respiration are reduced, and dyspnoea may result. The impulse of the heart may be felt in the third intercostal space ; the twisting of the heart may temporarily produce a pulmonary systolic murmur. Cardiac irregularity, palpitation, and attacks of faintness may result. The upper border of hepatic dullness may reach the fourth, third or even second intercostal space in front ; the right base is dull behind, owing to the liver being pushed up and the lung compressed. Bronchitis tends to develop, and the engorgement of the lung may in rare cases give rise to hæmoptysis. A pleural effusion may be suspected, but the upper limit of dullness is altered on taking a deep breath if it is due to the liver being pushed up, and the increased dullness diminishes or disappears when the patient lies on his face ; in pleural effusion the dullness is higher in the axilla than behind, but this is not the case if it is due to an abnormally high position of the liver.

The pelvis and renal regions hold a considerable amount of fluid, so that no accumulation occurs in the flanks until at least a litre is present in the abdomen. An area of dullness is, however, found in the most dependent part of the abdomen if the knee-elbow position is assumed. As more fluid collects the resonant note in the flanks is replaced by dullness, but the change may be delayed if there is much gas in the colon. The level of dullness now gradually rises and spreads over the pubes towards the umbilicus. On turning from one side to the other the most dependent part remains dull.

This is not, however, absolutely pathognomonic of ascites, as similar movable dullness may occur in chronic obstruction of the small intestines.

In chronic peritonitis the mesentery may be so shortened that the intestines are unable to float on the fluid; the fluid then accumulates in front of the intestines, and the highest part of the abdomen is dull.

A characteristic fluid thrill is felt when one side of the abdomen is sharply flicked by the fingers of one hand, whilst the other hand is placed flat upon the opposite side of the abdomen. When the patient is very fat, or the abdominal wall is cedematous, a similar but less marked sensation may be produced; in doubtful cases the hand of an assistant should, therefore, be pressed perpendicularly over the middle line of the abdomen, as this prevents the transmission of the impulse through the abdominal wall, but not through the fluid contents of the abdomen.

When the liver or spleen is enlarged and hard, or when an abdominal tumour is present, the sensation produced by dipping the tips of the fingers suddenly through the fluid on to the solid organ, which may jump away from them, is most characteristic.

Diagnosis of Ascites.—Confusion has often occurred between ascites and a large ovarian tumour. The history of the development of the abdominal swelling may help the diagnosis. In many cases the outline of an ovarian tumour can be definitely felt, and its pelvic attachments can be recognised by vaginal examination. The antero-posterior enlargement is greater than the lateral bulging, whereas the reverse is the case in ascites; the maximal girth is below the umbilicus instead of at the umbilicus or above; the umbilicus, which is normally and in ascites an inch nearer the pubes than the ensiform cartilage, is proportionately farther from the pubes; and the distension on one side is often greater than the other instead of being uniform.

Diagnosis of Cause of Ascites.—In cirrhosis of the liver the fluid collects rapidly, and the patient is obviously ill; in chronic peritonitis the accumulation on the first occasion is generally very gradual, and the patient may be otherwise well. An enlarged spleen or the occurrence of hæmatemesis points to cirrhosis, granular kidney to chronic peritonitis. A patient with ascites due to cirrhosis alone rarely survives the performance of paracentesis more than two or three times, as his general health has already greatly deteriorated by the time that ascites develops. If tapping is frequently performed, chronic peritonitis is therefore probably present, even if other evidence indicates that the patient is also suffering from cirrhosis. Tuberculous peritonitis is rare in adults, except as a complication of cirrhosis of the liver and when secondary to tuberculous Fallopian tubes. In children ascites due to cirrhosis is very likely to be mistaken for tuberculous peritonitis. Evidence of tuberculous disease in other parts of the body, solid masses palpable in the abdomen or on rectal examination, pain and tenderness in the abdomen except over the liver, and induration and redness of the umbilicus point to tuberculous peritonitis. The fluid is generally turbid, the specific gravity is above instead of below 1015, and lymphocytes are present.

In malignant peritonitis there is generally evidence of the primary disease in some other organ, and nodules may be felt in the abdomen, in the neighbourhood of the umbilicus, or in the middle line above it, and enlarged glands may be present. The spleen is not enlarged, emaciation is generally greater than in cirrhosis, and, except when the primary disease is in the stomach,

there is no hæmatemesis. A rectal and vaginal examination are particularly important, as ascites, which may recur very frequently, sometimes results from ovarian tumours. In a doubtful case the diagnosis may become clear after paracentesis, when the large hard liver and spleen may be felt in cirrhosis, and an irregular enlargement of the liver, but no splenomegaly, in cancer of the liver. In malignant disease the fluid may contain cancer cells; it is more often hæmorrhagic than in tuberculous peritonitis or cirrhosis.

Rapid development of ascites, with enlargement of the spleen and sometimes hæmatemesis, suggests portal thrombosis; if symptoms pointing to cirrhosis are already present, it is probably secondary to this, and even in their absence it may be secondary to latent cirrhosis.

An examination of the circulatory system and the urine should prevent confusion between ascites due to cirrhosis and that due to heart failure or kidney disease; but these conditions may be associated together.

Treatment.—A salt-free diet should be given, as ascitic fluid never contains less than 8 grammes of sodium chloride in each litre; if the quantity of salt taken in the day is reduced to 0·8 gramme, less than 100 c.c. of ascitic fluid can collect during the same period, as the urine always contains some salt, and the percentage in the body fluids never falls greatly below the normal. The quantity of salt and water retained can be still further reduced by giving 2 drachms of calcium chloride 3 times a day for 10 to 12 days, and then injecting 1 c.c. neptal or other similar mercurial preparation in order to stimulate the kidneys to excrete salt. With this treatment, which can be repeated periodically, the ascites may disappear, but unfortunately it is ill-borne by many patients and is by no means always effective.

The bowels should be kept well open, but severe purging weakens the patient and is likely to aggravate the catarrh of the alimentary canal, which is often already present. Epsom salts, which also promotes biliary drainage, is the most suitable aperient.

Diuretics are much more valuable as preventatives when the fluid first appears or after it has been removed than as curatives when a large quantity is present, as the pressure on the renal veins makes the kidneys less active, and an enormous quantity of fluid has to be excreted by them before the accumulation can disappear, whereas comparatively little urine need be passed to prevent its re-accumulation after tapping. Addison's pill of 1 grain each of powdered digitalis leaves, powdered squill root and blue pill, may be given for two days before paracentesis is performed, so that its action can come into play at once and not be delayed until the fluid has already begun to collect again, as the accumulation of fluid is most rapid immediately after paracentesis.

Attempts have been made to increase the collateral circulation between the portal and the general venous systems by operative means, on the assumption that ascites is a result of portal obstruction. The peritoneum over the liver and diaphragm is scraped and the omentum introduced between them, the abdomen being drained and the patient kept in the sitting position so that no fluid can intervene between the roughened peritoneum and prevent adhesions from forming. Great improvement occurs in a small proportion of cases, but in the majority little or no benefit results, and death shortly after the operation is not infrequent. The unsatisfactory results of

operation are hardly surprising, as portal obstruction is rarely the sole cause of ascites. Moreover, there is a distinct danger of increasing toxæmia by allowing an increased proportion of intestinal poisons to enter the general circulation without passing through the liver, which retains some of its antitoxic powers to the end.

Paracentesis should be performed at an early stage, as soon as the accumulation of fluid causes discomfort or seriously interferes with the digestion, circulation or respiration. Hæmatemesis is a further indication, as paracentesis reduces venous engorgement. The trocar should be inserted in the middle line between the umbilicus and pubes or in the flank. Care must be taken to avoid the liver and spleen. A trocar and tube of moderate bore should be used, as the very fine Southey's tube formerly employed tends to become blocked and the discomfort caused by the paracentesis is needlessly prolonged.

ARTHUR F. HURST.

SECTION X

DISEASES OF THE LYMPHATIC SYSTEM

DISEASES OF THE LYMPHATIC VESSELS

(i) DISEASES OF THE THORACIC DUCT

APART from obstruction of the duct, caused by intrinsic or extrinsic tumours (usually malignant in nature), and less often by tuberculosis, aneurysm and lymphadenoma, lesions in this situation are rare and are very difficult of recognition during life. The results of obstruction are chylous pleural effusion and (or) chylous ascites. Since chyloform ascites may occur without obstruction to the thoracic duct, as in tuberculous peritonitis, peritoneal carcinomatosis and even in cirrhosis of the liver, the presence of a milky pleural effusion is better evidence of a thoracic duct lesion than is a milky ascites. But even here the diagnosis is by no means certain on this fact alone. Chyluria, with chylous oedema of the genitals and lower extremities, if concurring with one or both of the above do, however, make diagnosis of obstruction to the thoracic duct almost certain.

(ii) DISEASES OF THE LYMPHATIC VESSELS

(a) *Lymphangitis*.—Acute inflammation of the smaller lymphatics is a very common infection, and is mainly of surgical significance. When present in septicæmia, however, its importance lies in the fact that it indicates the area of primary septic infection, or that pyæmic metastases are threatening in the neighbourhood of the inflammation. The appearance is that of reddish lines on the skin, running in the long axis of the limb, or of a red blush, here or elsewhere, associated with pain, tenderness and slight oedema. Chronic lymphangitis is usually tuberculous or syphilitic in nature.

(b) *Lymphangiectasis*.—This condition is usually the result of obstruction of the larger lymph vessels, causing dilatation of the smaller radicle, as by carcinoma, scar tissue, etc., or by infiltration of the walls of the vessels by tubercle or syphilis. *Elephantiasis* is a chronic affection, usually of one or both legs, leading to great increase in size of the limb. It may be congenital or acquired. In the latter case the condition may be due to infection by *Filaria sanguinis*, which causes lymph stasis and also inflammation of the skin and subcutaneous tissues.

DISEASES OF THE LYMPH NODES

A. LOCAL

(i) *Acute lymphadenitis* is generally associated with acute lymphangitis and is due to the same causes—acute septic inflammation of the skin or mucous surfaces of the part drained by the lymphatics affected. The lymphatics associated with the fauces are those most often involved, for obvious reasons. The tender and swollen nodes may suppurate, in which case the inflammation spreads, leading to peri-adenitis and involvement of the skin.

(ii) *Chronic lymphadenitis* is more often due to tuberculosis than to pyogenic infection. Here, again, the faucial group is most often affected. The bronchial and mesenteric groups are, however, quite commonly affected.

B. GENERAL

(i) *Acute Generalised Lymphadenitis*.—This occurs in every one of the acute infectious diseases, but is specially frequent, and therefore of special diagnostic importance, in German measles, measles, scarlet fever and diphtheria. In glandular fever there is generalised lymphadenitis associated with mononucleosis.

(ii) *Chronic Generalised Lymphadenitis*.—This is seen in the “secondary” stage of syphilis, and also in tuberculosis. In the latter infection the character of the nodal enlargements varies with the histological reaction to the bacillus and with the tendency to caseation, which may be well, or ill, marked. It is in cases in which caseation is delayed, or absent, that the diagnosis from lymphadenoma is sometimes very difficult, or quite impossible, in the absence of biopsy.

(iii) *Neoplastic Infiltration*.—Both carcinoma and sarcoma may cause generalised (as well as local) lymph-node involvement.

HODGKIN'S DISEASE

Synonym.—Lymphadenoma.

Definition.—A disease characterised by painless, progressive enlargement of lymph nodes, usually beginning in one group and spreading to other groups, and associated with hyperplasia of lymphoid tissue in the spleen, liver and other organs, with anæmia.

The disease appears definitely to be a specific entity. Its causation is unknown. In nosology it is by some placed amongst the microbic infections, and by others amongst the neoplasmata; it has affinities with both of these processes.

Ætiological Factors.—The disease occasionally follows upon known infections—pyogenic, tuberculous or syphilitic—but in these cases it would appear to be of the nature of a secondary infection rather than an expression of any one of these diseases. It may co-exist with tuberculosis. Though it may arise at almost any age, the chief incidence is during the first four decades

of life. It is about twice as common in males as in females. Though sometimes seen in two or more members of the same family, there seems to be little or no real hereditary tendency.

Pathology.—The enlarged lymph nodes tend to remain discrete, and the capsule of the node is rarely, if ever, infiltrated. The masses are sometimes very large and may weigh several pounds. Individual nodes are seen to be of a pinkish-grey colour, smooth, "leathery" to the feel and, on section, show yellowish strands passing in from the capsule, with rather translucent whitish tissue between them. Areas of necrosis are unusual. Microscopic examination reveals great proliferation of the reticular endothelium, hyperplasia of the lymphoid cells and a mixture of large hyaline cells, plasma cells and eosinophil leucocytes. Some of the endothelial cells are very large and are multinuclear. These cells have some resemblance to giant cells, but their outlines are more regular and their nuclei are superposed and placed in a mass near the centre of the cell rather than ranged around the periphery. The presence of these large multinuclear endothelial cells, together with eosinophil cells, constitutes the most characteristic feature of the lymphadenomatous lesion histologically.

The *spleen* is generally enlarged at the time of death, but great enlargement, though it does sometimes occur, is unusual. The organ is quite firm, preserves its natural contours, and adhesions are often present. The surface is sometimes slightly nodular. On section the well-known "hardbake" appearance is seen—whitish-grey areas (of lymphadenomatous material) embedded in a dark red matrix (of spleen pulp).

The *liver* is the organ most often affected next to the spleen. The deposits are found to lie chiefly in the portal canals. There is usually associated fatty change.

Of other organs and tissues, the lungs, kidneys, bones and intestines are those chiefly affected.

Symptoms.—In the great majority of the cases the first symptom is the appearance of enlarged lymph nodes in the neck. The first nodes to be involved are more often in the posterior than in the anterior triangle. At this time the patient is not ill, nor does a full investigation, as a rule, discover signs of disease elsewhere; there is little or no *anæmia*. Other, but less common, situations for the initial node swellings are the axillæ, the groins, the mediastinum and the abdomen. There is usually an interval of some months before general symptoms appear, and their onset is usually insidious. In some cases, however, the general symptoms advance rapidly. There is an acute type of the disease, associated with early generalisation of the node involvements, and if the original local lymph node enlargement is overlooked, the simulation of some such acute infection as miliary tuberculosis may be very close.

The features of the lymph node swellings are important. They soon become visible. They are painless, insensitive, and in the early stages of the disease they mobilise easily. To the feel, the nodes are firm and leathery. They tend to remain discrete, without involvement of the capsule and therefore without coalescence. The skin is only rarely involved; and when it is, or when, with equal rarity, the nodes undergo caseation or suppuration, this is due to secondary infection by pyogenic organisms or by tubercle. After a while the enlarged nodes tend to become massive tumours, and certain of

the above features change—their mobility lessens and the individual nodes are difficult to recognise.

Two sets of symptoms now become added to the initial superficial node enlargements—the general symptoms of the disease, and symptoms referable to pressure and infiltration of the lymphadenomatous tissue in different parts of the body.

The *general symptoms* include a sense of lassitude and weakness, shortness of breath on exertion, sweating and loss of weight. Pruritus is rather common and may be very intractable. The colour of the skin changes to a *café-au-lait* tint, and in some cases a well-marked general pigmentation develops. *Pyrexia* is quite common. The form most often seen is a mild grade of remittent pyrexia, similar to that seen in tuberculosis. Not at all infrequently, however, the pyrexia assumes an undulant character, and the recognition of this type of fever is of great importance in diagnosis. It is not at all uncommonly overlooked, especially if morning and evening charts are not kept. Sometimes the undulant feature is very marked, a wave of pyrexia of some ten to 14 days' duration is followed by an apyrexial period of somewhat shorter duration, when the pyrexial period is repeated, and so on. The symptoms wax and wane with the pyrexia, not only the general symptoms but, at times, symptoms of a focal kind. The writer has seen a case of this sort in which acute pulmonary symptoms were present, and the disease was thought to be a relapsing broncho-pneumonia. Such pyrexia as is here referred to is termed the "Pel-Ebstein type," after the two observers who first described it. There is a third, and less common, form of pyrexia: the continued type somewhat resembling typhoid fever. It occurs in severe and rapidly progressive cases.

The *anæmia*, though it may be severe, has not, despite tradition to the contrary, any special features, nor is the blood picture often helpful in diagnosis. The red blood count and the hæmoglobin estimate are those of a "secondary" anæmia. The white cells vary much in number and in kind. Leucopenia is present in some of the more acute cases, and is occasionally a striking accompaniment of the pyrexial phases in a marked Pel-Ebstein fever. In the majority of cases, however, the leucocyte count shows a moderate rise (10,000 to 20,000). The absolute eosinophil count quite frequently lies above the top figure of the range in health (400), and this fact may therefore be of some diagnostic help.

Focal symptoms, as already stated, are due, in the main, to pressure by the lymphadenomatous masses. Mediastinal pressure causes distressing dyspnoea, cyanosis and stridor; laryngeal palsy may be bilateral and may require tracheotomy—in which case the operation may tax the resources of the most experienced surgeon. Enlarged hilum glands and invasion of the peri-bronchial tissues produce collapse of lung, pleural effusions (sometimes hæmorrhagic or chyliform), and bronchiectasis with hæmoptysis. Masses in the transverse fissure of the liver cause jaundice and ascites.

An interesting and not very uncommon complication is a paraplegia due to meningeal involvement about the lumbo-sacral region or the cauda equina.

Diagnosis.—This is from other causes of lymphadenopathy, both local and general, such as tubercle, syphilis, the less acute form of glandular fever, leukaemia and generalised neoplasmata. There are two diseases which confuse with Hodgkin's disease in particular: these are tuberculous adenitis.

and lympho-sarcoma. Especially does the uncommon form of tuberculosis, termed "endothelial," cause difficulty. In such circumstances *biopsy* alone may serve to establish the diagnosis. But even then the problems may not be solved, because the node removed may not show characteristic changes, being as yet inconclusive in its early morbid appearances or being too fibrotic. Care must be exercised in the choice of the lymph node to be excised: the one most easy to remove is not necessarily the best for diagnostic purposes.

Course and Prognosis.—Trousseau's description of the disease as having three stages—the stage of local lymph-node enlargement, the stage of general lymphatic enlargement, and the stage of cachexia—holds good for the great majority of cases. But cases may be acute throughout, the total duration not exceeding three months. In other instances, long periods of remission occur, and these, with modern irradiation methods of treatment, are much more frequently seen nowadays than formerly. The average duration of the disease is perhaps about five years. Patients in whom the diagnosis has been well established may be found in moderately good health ten years later. But complete arrest must be quite rare, if, indeed, it occurs at all. Rather rapid "lighting up" in a quiescent case is one of the striking features of the disease, and though the condition may be, again and again, stabilised by treatment, the level of health after each active phase has passed is found to be lower than it was previously.

Treatment.—Excision of the enlarged nodes, formerly much practised, has to-day been almost completely abandoned in favour of irradiation methods, using either X-Rays or radium for the purpose. Of the two methods, X-Rays appear more generally useful. It is at present the usual custom to use light and frequent doses, irradiating the nodes, the spleen, the mediastinum and other parts known to be affected, mapping out the areas to be treated and selecting the angles of application with great care. These light doses may be given daily over a period of two or three weeks, and repeated after an appropriate interval. A course of arsenic may now be administered, and nothing seems better for this purpose than the old-fashioned Fowler's solution in an alkaline draught. General hygienic measures should be attended to throughout the treatment.

STATUS LYMPHATICUS

Synonym.—Lymphatism.

Under this term are classed, somewhat loosely, a number of cases met with in which there is hyperplasia of the lymphatic tissues in the body. The note of dramatic significance is given to these cases because, in them, sudden death is prone to occur, whether during anæsthetic administration or otherwise.

Since the thymus is found to be enlarged with great constancy in such patients, considerable importance attaches to this part of the picture, though it is probable that the essential nature of the diseased state is much more general, and that such local hyperplasia alone, though it has serious possibilities, is not responsible for more than a proportion of the fatalities.

Though the diagnosis of thymic hyperplasia is nowadays greatly assisted by X-Ray examination of the thorax, by far the majority of instances of lymphatism are only discovered in the post-mortem room. Children who present

a pallid and flabby facies are by no means necessarily "lymphatic" in the sense of the word here used. Nor does the presence of "thymic asthma" necessarily denote more than the local lesion of an enlarged thymus. In other words, lymphatism always presents thymic hyperplasia as one of its features, but demonstration of thymic enlargement, whether before or after death, by no means proves the existence of lymphatism. The real nature of this latter condition is quite unknown.

MIKULICZ'S DISEASE

Definition.—A chronic inflammation of the salivary and lachrymal glands of unknown origin. There is considerable and bilateral enlargement of the glands, due to hyperplasia of the lymphoid elements rather than of the gland structure proper. Before a case is regarded as justly observing the name of Mikulicz's syndrome, it is necessary to exclude leukæmia, Hodgkin's disease, tuberculosis and syphilis, in all of which diseases enlargement of the salivary glands may occur. But, when this is done, there still remain a few cases of salivary hyperplasia in which the patient's general health is unaffected. The condition is very intractable, but iodine given internally, and irradiation of the diseased glands, appear to cause amelioration.

HORDER.

SECTION XI

DISEASES OF THE BLOOD

THE blood is sometimes regarded as the mixed secretion or product of the blood-forming organs. For the purposes of description and for the better understanding of the changes in disease, it is more convenient to think of the blood and blood-forming organs as composed of three distinct systems or tissues: (1) the red cells and their precursors, sometimes known as the erythron; (2) the white cells and the immature cells from which they arise; (3) the platelets and the megakaryocytes. These three systems of cells exist side by side in the plasma and bone-marrow, and are often affected simultaneously by disease, but they are to a large extent independent of each other. Before discussing separately the three systems of cells and their diseases, it will be convenient to say a few words about the total volume of the blood.

THE BLOOD VOLUME

✓ The total volume of the blood is about 90 c.cm. per kilogram of body weight, i.e. some 6000 c.cm. in an average individual, or about one-eleventh of the body weight. Of this volume the cells constitute about 42 per cent., the remainder being plasma. The volume of blood is very constant at rest, but it is increased on excitement or exertion by contraction of the spleen, which acts as a reservoir of blood. The blood volume is moderately diminished in anæmia; it is moderately increased in the splenomegalics, in leukæmia and in erythrocytosis, and greatly increased, even to two or three times the normal, in erythræmia. There is a slight increase in œdema, due to an associated œdema of the blood, but no change in arterial hypertension. The blood volume is moderately increased in pregnancy, in order to allow for the foetal circulation.

Of great importance in practice are the conditions in which the volume of circulating blood is suddenly and considerably diminished. The chief causes are hæmorrhage, surgical shock, the depletion of fluid from the body which occurs in severe burns, diabetes, cholera and similar diseases, and profound toxæmia, such as occurs in bacterial infections, snake-poisoning, anaphylaxis and similar states. The patient becomes collapsed, he complains of thirst, the skin is pale, cold and moist, the pulse rapid and almost imperceptible, and the blood pressure low. Anuria develops and adds the further complication of renal insufficiency. Occurring during an acute infection, the symptoms are often mistaken for acute heart failure, but they are really due to vasomotor paralysis, stasis of blood in the capillaries and deficient volume of circulating blood. There can be little doubt

that this vasomotor paralysis is sometimes precipitated by the intravenous injection of antisera and chemicals in acute diseases for which there is no specific treatment, by the transfusion of unsuitable cases, and by the neglect of such simple measures as the exhibition of large quantities of fluid and glucose by mouth.

The degree of shock in hæmorrhage depends largely on the rate of bleeding. A sudden hæmorrhage of 1500 to 2000 c.cm. may be fatal, while as much as 60 per cent. of the total amount of blood may be lost without death if the hæmorrhage is prolonged over 24 hours or more. The blood count is of little value in determining the patient's condition, inasmuch as the concentration of the blood may be unaffected in the early stages. Reliance should be placed on the symptoms and the blood pressure; a systolic pressure below 80 mm. is a serious sign. Treatment is by the transfusion of 500 c.cm. or more of blood, if necessary repeated at a short interval. A 6 per cent. solution of gum acacia may be employed, but is much less satisfactory. In shock not due to hæmorrhage, the first step in treatment is the slow intravenous administration of 50 c.cm. of a 50 per cent. solution of dextrose. The hypertonic dextrose solution rapidly draws fluid from the tissues into the blood vessels and temporarily adjusts the blood volume to the capacity of the vascular bed. This method of treatment usually requires to be supplemented soon after by introducing 500 to 1000 c.cm. of saline or glucose saline into a vein, especially when there is dehydration. The patient should be kept warm and inhalation of oxygen may be indicated. The injection of cardiac stimulants should be avoided, as they probably do more harm than good.

THE RED BLOOD CELLS

The red blood cells are biconcave discs with a mean diameter of 7.20 microns (6.7 to 7.7 μ), a mean volume of 85 cubic microns (75 to 95 $\mu\mu$), and a mean corpuscular hæmoglobin content of 29 micromicrograms¹ (26.5 to 31.5 $\gamma\gamma$). Their size and shape are adapted to the carriage of hæmoglobin and the supply of oxygen to the tissues. The blood of a healthy young male contains about 5.5 millions of red cells per c.mm. and 16 grams of hæmoglobin per 100 c.cm.; of a healthy female about 4.75 millions of red cells per c.mm. and 14 grams of hæmoglobin per 100 c.cm. Fluctuations of a million red cells per c.mm. and of a corresponding amount of hæmoglobin may be observed in accurate counts on the same individual at different times of the day, owing to the varying delivery of new cells into the blood stream and the changing content of the splenic reservoir. For purposes of calculation the normal red cell count is taken as 5 million cells per c.mm., and the corresponding amount of hæmoglobin (14.5 grams per 100 c.cm. of blood) is taken as 100 per cent. hæmoglobin. The colour index measures the average amount of hæmoglobin contained in the red corpuscles of a sample of blood, and is calculated from the formula,

$$\text{Colour index} = \frac{\text{Hæmoglobin per cent.}}{\text{Number of red cells per cent. of the normal}}$$

¹ A micromicrogram is the millionth of a millionth part of a gram (1 gram $\times 10^{12}$) and is abbreviated by the Greek letters gamma ($\gamma\gamma$).

The red cells in any sample of blood are never absolutely equal, but show a certain amount of variability in size, or anisocytosis. The degree of variability, or anisocytosis, is often increased in anæmia and may be of diagnostic significance. The mean diameter of the red cells and their variability is determined by measuring the diameter of 500 successive red cells under the microscope on a stained thin smear. The results are then plotted on squared paper, with the number of cells counted as ordinates and the diameter of the cells as abscissæ, to obtain what is known as a red cell diameter

FIG. 21.—Frequency distribution curves of red cell diameters in health and disease (Price-Jones curves):

distribution curve, or Price-Jones curve (Fig. 21). Abnormal variability in the size of the cells will be shown by a widening of the base of the curve. Cells which are larger than normal and fall to the right of the limits determined on healthy individuals are called megaloeytes. Small cells which fall to the left of the limits of health are called microeytes. A cell of normal diameter is a normocyte.

The red cells are formed in the bone-marrow, probably within the lumen of capillary vessels which connect the sinuses to each other (Fig. 22). The most primitive cells, which are formed by mitosis from the endothelial cells

lining these intersinusoidal capillaries, are known as megaloblasts. They are distinguished not only by their size but also by their large, reticular nucleus and by the fact that their cytoplasm is often basophil. Successive divisions of the megaloblasts give rise to the normoblasts, which are smaller cells, with round deep-staining, often pyknotic nuclei, and usually richer in hæmoglobin than the megaloblasts. The normoblasts lose their nuclei by extrusion or solution, but for a time they still contain remnants of the original basophil cytoplasm, which gives the red cell a bluish tinge in ordinary stained smears (diffuse basophilia or polychromasia). Certain dyes, such as brilliant cresyl blue, when brought in contact with the fresh-drawn blood, precipitate this basophil cytoplasm in a network or reticulum, and on this account these immature red cells are called reticulocytes. Polychromasia and reticulocytosis are identical conditions revealed by different stains. The normal reticulo-

FIG. 22.—Schematic diagram of formation of red cells

cyte count is $\frac{1}{4}$ to 2 per cent. A similar precipitation may occur *in vivo* when poisons, such as lead, circulate in the blood stream and the reticulum becomes visible in ordinary preparations (punctate basophilia).

Developing within the hæmopoietic capillary, the red cells dilate the lumen, but the capillary does not normally open to the circulation until the red cells are mature. This is because the membrane of the young cells is sticky and they adhere to one another. The stickiness persists till about the time when the reticular substance disappears from the cell. The plasma then filters between them and they are swept into the circulation. Just as the capillaries of other organs vary greatly in activity with the activity of the tissue they supply, so also the capillaries of the marrow. In the marrow they offer not merely a reserve capillary bed but the potentiality of an enormous hyperplastic response. In healthy adults few or no megaloblasts are visible in the marrow, as the ordinary wear-and-tear of red cells

is easily made up by proliferation of normoblasts. When blood destruction is greatly increased, the marrow becomes hyperplastic and the megaloblasts increase in number. Other disease-processes interfere with the normal ripening of megaloblasts into normoblasts, or of normoblasts into normocytes, in such conditions the marrow becomes crowded with cells of the type whose further development is arrested, giving rise to a megaloblastic or normoblastic hyperplasia of the marrow, although few ripe cells are entering the circulation. Whenever the bone-marrow is hyperplastic, whether from increased production of cells, or from arrest of their complete maturation, nucleated red cells may appear in larger or smaller numbers in the peripheral blood.

The adult red cell is a lifeless hæmoglobin container, and it is gradually worn out by the buffeting in the circulating blood. As the cells age, they become malformed and finally broken into fragments which are engulfed by the phagocytic cells of the liver, the spleen and other tissues. These malformed red cells are called poikilocytes. In all forms of anæmia the cells put into circulation are less perfect than in health, and poikilocytosis more rapidly develops. In any severe anæmia the patient should be put to bed, if only to diminish this circulatory wear-and-tear. The phagocytosed fragments are split into their constituent materials—iron, bilirubin, lipoids and other substances, which are in part excreted, in part used again for the manufacture of new red cells. Excessive destruction of red cells gives rise to an accumulation of bilirubin and iron in the blood and tissues.

The classification of the anæmias is fraught with difficulty. The views held by hæmatologists as to their ætiology have changed greatly in recent years, and the new knowledge is still imperfect and unsuitable for dogmatism. We may divide anæmias by their pathology as follows :

A. Anæmia due to diminished blood formation.

1. Anæmia from depression of the function of the erythropoietic tissues by infection, toxæmia, cachexia or malignant disease.
2. Anæmia from disturbance of the normal processes of maturation of the red cells. To this important group, which is usually the result of a deficient supply of hæmopoietic material to the bone-marrow, I have given the name anhæmopoietic anæmia.
3. Anæmia from aplasia of the erythropoietic tissues.

B. Anæmia due to increased blood destruction.

1. Anæmia from hæmorrhage.
2. Anæmia from hæmolysis.

It will be more convenient to work on a clinical basis, and to consider first the anæmias which occur as a complication of other well-recognised diseases, and secondly those which are best regarded as independent diseases of the erythropoietic tissues.

The student of hæmatology experiences many difficulties due to the confused state of the terminology and the different meanings applied to words at different times and by different authors. Anæmias were originally divided, on an ætiological basis, into the "primary" and the "secondary": a primary anæmia is one which may be regarded as a disease entity, such as Addison's anæmia, or acholuric jaundice; a secondary anæmia is one which is merely a symptom of some underlying disease. As the colour index in

secondary anæmias is usually low, the term "secondary anæmia" is sometimes used to mean anæmia of low colour index. This is a bad practice, which would justify us in speaking of chlorosis as a primary anæmia in the ætiological sense and a secondary anæmia in the hæmatological sense. If the term "secondary" is retained, it should be used in the strict ætiological sense and supplemented by the cause, as anæmia secondary to hæmorrhage, or anæmia secondary to infection. It is probably better discarded and replaced by the term "symptomatic." It is equally unnecessary and confusing to describe anæmias as chlorotic or pernicious in type. According as the colour index is high, normal or low, they are described as hyperchromic, orthochromic or hypochromic. They can also be classified by the size of the red cells into megalocytic, normocytic and microcytic anæmias. These two sets of terms correspond roughly with each other, but they are not absolutely interchangeable, and each should be used strictly according to definition. As the colour index is always determined, whilst the size of the red cells is not often measured, the former set will be more commonly employed.

THE SYMPTOMATIC ANÆMIAS.

Synonym.—Secondary Hypochromic Anæmia.

Definition.—A symptomatic anæmia is one which arises in the course of some other well-defined disease. The colour index is usually low and hardly ever above unity. In the rare cases in which the colour index rises above unity, the disturbance of the erythropoietic tissues is usually so profound that for practical purposes all the megalocytic anæmias can be regarded as definite diseases of the erythropoietic tissues.

Ætiology.—The most obvious cause of anæmia is hæmorrhage: acute hæmorrhage occurs most commonly from trauma, bleeding from the alimentary tract, and the accidents of child-birth; chronic hæmorrhage is often due to hæmorrhoids, menorrhagia, and in tropical countries hookworm disease. Hæmolysis is a rare event, but it may be induced by chemical poisons, or by infection by hæmolytic organisms, such as the *Streptococcus hæmolyticus* or the *Bacillus welchii*, or by malaria. Acute infections rarely produce much anæmia, but severe anæmia may develop in protracted septic infection, acute rheumatism, rheumatoid arthritis, and other subacute or chronic infections, such as typhoid fever. In my experience focal sepsis is seldom responsible for an anæmia. Tuberculosis causes little anæmia until the later stages, when hæmorrhage, suppuration or intestinal ulceration has occurred. Syphilis also is rarely the cause of anæmia, except in the more florid stages, or from involvement of the liver, or from paroxysmal hæmoglobinuria. Malaria has already been mentioned. Of the toxæmias responsible for anæmia, nephritis and lead poisoning are the most important. Malignant disease is one of the commonest causes of anæmia; it may act in various ways—hæmorrhage from a malignant ulcer, cancerous cachexia, and invasion of the bone-marrow. Anæmia which is due to mechanical limitation of the bone-marrow by tumours or tumour-like conditions, such as leukæmia, Hodgkin's disease, infective granulomata and kala-azar, is sometimes described as myelophthiotic anæmia, but this is an incorrect and unnecessary use of a word which is one of the synonyms for aplastic anæmia.

If the skeleton is stimulated by such metastases, or by other causes, to the formation of new bone and consequent encroachment on the marrow cavity, the term osteosclerotic anæmia may be used (p. 785).

Individuals differ greatly in their ability to withstand anæmising agencies and to repair loss of blood. The erythropoietic tissues in women appear to be more vulnerable than in men, and all the symptomatic anæmias except that due to malignant disease are commoner in the female sex.

Pathology.—Two factors can be distinguished in these symptomatic anæmias. The first is loss of blood by hæmorrhage or hæmolysis. This leads to hyperplasia of the bone-marrow, and an outpouring of new red cells to repair the deficiency. The colour index is low, because hæmoglobin regeneration lags behind the restoration of a normal cell count, and the reticulocyte count is increased to 5 or 10 per cent., or higher. Chronic and repeated hæmorrhage may so exhaust the hæmatinic reserves that the body cannot repair the hæmoglobin deficiency, the anæmia remains torpid, and the reticulocyte count is low; rapid recovery occurs on the exhibition of large doses of iron. The second factor in the symptomatic anæmias is depression of the erythropoietic tissues by toxæmia; the marrow becomes hypoplastic, and may even degenerate completely. The output of new red cells is diminished, the reticulocyte count is low, and the colour index a little below unity. Usually both factors are present in varying degree, and the blood picture is modified accordingly. The white cells and platelets are normal or increased in number, unless the marrow is greatly depressed. The other tissues generally show anæmia, cedema and fatty change.

Symptoms.—The symptoms, other than those of the primary malady, depend on the speed with which the anæmia develops. In acute anæmia from hæmorrhage or blood destruction there is extreme exhaustion and true shock, with faintness or syncope, air-hunger, sweating and thirst. The alarm induced in the patients and attendants by a large hæmorrhage is an important factor in this shock, and the amount of blood lost is usually over-estimated. In chronic anæmia, on the other hand, it is surprising how well the patient may feel. No complaint may be made with a hæmoglobin of 40 per cent., and only of undue fatiguability with a hæmoglobin of 20 per cent. Inquiry elicits such symptoms as dyspnoea, palpitations, anginal pain, fainting attacks and cedema of the extremities. The pallor is best seen in the conjunctivæ or the palate; the skin is a bad guide, for it is often pale when there is no anæmia, and sunburnt and deceptively healthy when anæmia is severe. The pulse is rapid and the heart dilated, and systolic murmurs may be audible over the præcordium.

Prognosis and Treatment.—The prognosis and treatment are those of the primary disease. In acute anæmia the patient should be transfused if his condition is critical. In chronic hæmorrhagic anæmia iron is of great value. In the majority of the symptomatic anæmias it is possible to produce a normal blood picture for a time by iron, liver and repeated transfusions, and so bring the patient into condition for operation or similar treatment. Apart from such emergencies, it is doubtful whether the transient benefit of a transfusion is commensurate with its risks in patients suffering from toxæmia, while iron and liver may have little effect if the cause of the anæmia is not removed. The treatment of anæmia is discussed in detail at the end of this section.

THE ANHÆMOPOIETIC ANÆMIAS

The development of the red blood cells in the marrow has already been described. We may regard the marrow as a factory in which the cell bodies are manufactured and equipped with their cargo of hæmoglobin. An important group of anæmias appears to be due to a defective supply of raw materials to the marrow. At each stage of development certain substances are required for the completion of the next phase. The substances necessary for the differentiation of the megaloblasts from the primitive marrow cells have not been isolated. For the ripening of the megaloblasts into normoblasts, the active principle of liver and stomach extracts, which is possibly a break-down product of vitamin B, is known to be essential. For the further development of normoblasts into erythrocytes, iron, traces of copper and other minerals, vitamin C, thyroxin and probably other substances are essential. If any of these substances is not available, erythropoiesis is arrested and the patient becomes anæmic. When sufficient iron is not supplied, either from unsuitable diet or from diminished absorption from the alimentary canal, the normoblasts multiply and the marrow encroaches on the shafts of the long bones, but the cells fail to mature and few cells are delivered into the blood stream. Absence of the nitrogenous complex present in liver extract gives rise to a futile megaloblastic reaction, but again the delivery of mature red cells is diminished.

As these anæmias are due to deficient blood formation, they are called *anhæmopoietic*. According to the level at which erythropoiesis is arrested, the marrow may be normoblastic, megaloblastic, or aplastic, the associated anæmia being microcytic, megalocytic, or aplastic respectively. The reticulocyte count is low, and the white cells and platelets are normal or diminished. Remission of the disease is attended by an outpouring of reticulocytes in numbers directly proportional to the extent of the hyperplasia of the bone-marrow. This is called the *reticulocyte crisis*. Clinically these anæmias are frequently associated with glossitis, gastro-intestinal disorders and degeneration of the nervous system. The most important examples of this group are: firstly, those which are due to iron deficiency and are microcytic in type—the nutritional anæmia of infancy, simple achlorhydric anæmia and probably chlorosis; and secondly, pernicious anæmia and allied megalocytic anæmias. Sometimes more than one deficiency may be present, but in general it is surprising how specific is the response to treatment, and grape-shot therapy is rarely excusable.

1. NUTRITIONAL ANÆMIA OF INFANTS

Synonym.—Anæmia of Prematurity. *due to deficiency*

Anæmia of moderate degree is present in practically all infants, whether fed by the breast or artificially. It may become very severe, especially in twins and premature babies, who come into the world with a small store of iron, or after intercurrent infection, or when suckling is protracted beyond the normal period. It disappears spontaneously on the adoption of a mixed diet. Helen Mackay has made a comprehensive and illuminating study of this anæmia, which appears to be a pure mineral deficiency, resultant from

the low iron and mineral content of the milk, and reparable by inorganic salts of iron. In severe cases the hæmoglobin is reduced to 30 per cent. or less. The colour index is low. Death may occur, especially when the anæmia is exacerbated by intercurrent infection. Repair of the anæmia is followed by increased resistance to infection. Treatment is by iron and ammonium citrate, in a dosage of 4½ to 9 grs. daily. It is essential to accustom the infant to the iron slowly, as the sudden administration of the full dose may cause colic and diarrhœa. For this reason administration is started very gradually, particularly in young infants. In bottle-fed babies the solution of iron and ammonium citrate is added to the milk, or proprietary foods containing iron are used. The mother should be warned that the stools will be dark. There are few babies, whether breast-fed or bottle-fed, who are not improved by the prescription of iron.

2. CHLOROSIS

This disease was very common in adolescent females until the end of last century, but it has now completely disappeared. Its aetiology and the reason for its disappearance are alike unknown. It seemed to be in some way connected with the inception of the reproductive period, and usually disappeared spontaneously after marriage or parturition. The name was given on account of the greenish tinge often present in the complexion. The colour index was low, and the white cells and platelets were unaffected. It was cured by large doses of iron. Hypochromic anæmias arising spontaneously in childhood and adolescence are still often diagnosed as chlorosis. It is undecided what relation they bear to this disease, for they never show the greenish colour of the skin, and they can usually be explained on nutritional grounds. In my experience they are equally common in males and females, unlike the classical chlorosis, which was confined to girls.

3 IDIOPATHIC HYPOCHROMIC ANÆMIA

Synonyms.—Simple Achlorhydric Anæmia; Chronic Microcytic Anæmia of Women; Late Chlorosis; Achylic Chloranæmia.

Definition.—A disease occurring almost exclusively in women, characterised by chronic anæmia of low colour index, achlorhydria, frequently glossitis and occasionally splenomegaly.

Ætiology.—This is the commonest of all the idiopathic anæmias. The most typical examples are seen in women between the ages 20 and 50, and the condition usually improves spontaneously after the menopause. A few cases are met in both sexes in childhood and in old age. It is rather more common in hospital than in private practice, probably because of the higher birth rate and the poorer nutrition. The chief cause of the anæmia is achlorhydria, which leads to diminished absorption of mineral elements, and especially of iron from the food. In rare cases, which are clinically indistinguishable, the gastric secretion is normal, but there is intestinal dyspepsia, suggestive of impaired absorption of iron from the intestine. Important aggravating factors are defective diet, meat and other iron-containing foods not being eaten in sufficient amount; and pregnancy, lactation and menorrhagia. There is a strong hereditary tendency; not infrequently

cases of idiopathic hypochromic anæmia, pernicious anæmia and subacute combined degeneration of the spinal cord occur in different members of the same family as manifestations of the common inheritance of achlorhydria. An important group of cases is the result of gastro-enterostomy and similar operations, or accidents, which neutralise or abolish the gastric secretion.

Pathology.—The bone-marrow is moderately hyperplastic, and microscopic examination shows an increased number of normoblasts. The spleen is moderately enlarged by a simple hyperplasia. The epithelium of the tongue and pharynx may show a leucoplakial degeneration. The other organs exhibit the usual effects of a simple anæmia.

Symptoms.—Symptoms may first be complained of after a pregnancy, or an influenzal attack, but careful inquiry often elicits the information that the patients were always pale, or that they have previously come under medical care for anæmia. Symptoms fall into two categories. First there are those due to anæmia: general weakness, headaches, palpitation and dyspnoea; præcordial pain on exertion is common and may be of anginal severity; slight œdema of the ankles occurs, but anasarca or ascites is unusual. The second category of symptoms is composed of those due to dyspepsia, probably the result of the achlorhydria: lack of appetite, epigastric pain and distress, retching and vomiting after meals, flatulence and bilious attacks; constipation is frequent, but diarrhœa is unusual.

Pallor is the most obvious and may be the only sign; occasionally the skin is yellow or pigmented, but there is never any jaundice. The nails are frequently brittle and painful, and occasionally they are hollow and depressed like a spoon (koilonychia); on cure of the anæmia the new nail exhibits the normal contour and consistence. Glossitis is present in about half the cases. It is often painless and unknown to the patient, but on the other hand it may be the chief complaint. In the active stages the tongue is reddened and excoriated, and vesicles may appear and break down to form shallow ulcers. In the chronic and quiescent stages the filiform papillæ are destroyed, leaving a smooth bald tongue. The inflammation may spread to the buccal mucosa and to the corners of the mouth and lips, conditions known as stomatitis and perlèche. Passing backwards to the pharynx, the affection produces huskiness and, when the nerve terminals in the pharynx are involved, a most troublesome dysphagia, which may be the presenting symptom (the Plummer-Vinson syndrome, see p. 543). Idiopathic hypochromic anæmia is, in my experience, much the commonest cause of the Plummer-Vinson syndrome. The spleen is palpable in about one-quarter of all cases of idiopathic hypochromic anæmia, but it is rarely greatly enlarged; more seldom the liver is palpable. The other signs are those of anæmia. There are no changes in the spinal cord, but functional nervous disorders, nervous breakdowns, aphonia, and pruritus frequently occur. The menses are more often scanty than heavy; owing to relaxation of the anæmic uterus these women are, however, prone to postpartum hæmorrhage and to menorrhagia about the menopause.

A test meal reveals achlorhydria or extreme hypochlorhydria; the gastric ferments are still present, though often reduced in amount. The achlorhydria is a permanent abnormality, preceding the anæmia and remaining when it is cured. The existence of cases which in every way resemble simple achlorhydric anæmia, except that the test meal is normal, has already been dis-

cussed. The anæmia is of low colour index, and the red cells are usually smaller than normal. It is essentially a hæmoglobin deficiency, and often the red cell count is little below normal. The white cells and platelets are normal; an occasional normoblast may be present. Reticulocytes are within normal limits, and van den Bergh's reaction is negative. A typical count is: red cells, 3,500,000 per c.mm.; hæmoglobin, 35 per cent.; colour index, 0·5; white cells, 7000; differential count normal. In exceptional cases the red cells may fall nearly to a million and the hæmoglobin to 15 per cent. On treatment with iron there is a reticulocyte crisis, most marked in the most anæmic cases, but seldom exceeding 15 per cent., the red cells are rapidly restored to the normal number, and the hæmoglobin is more slowly regenerated. There may be a transient erythrocytosis during the recovery phase.

Complications and Sequelæ.—The Plummer-Vinson syndrome is the most important complication, occurring in about 15 per cent. of cases. There is evidence that the changes in the epithelium of the tongue and pharynx predispose to malignant disease, and epithelioma of the tongue and carcinoma of the hypopharynx develop in a few instances. There is a risk of transition into pernicious anæmia, most marked in women with a family history of that disease, but in my experience the risk is not great. Thrombosis is a rare complication.

Diagnosis.—Many cases are overlooked, or diagnosed as debility or functional nervous disorder, on account of the vagueness of the symptoms. Such mistakes are only to be avoided by examining the blood. Care should be taken to exclude other causes of anæmia, more especially malignant disease. The symptoms may suggest pernicious anæmia, but the low colour index and negative van den Bergh reaction are incompatible with this diagnosis, as also is the failure to respond to treatment by liver or stomach.

- 1) In the rare disease aplastic anæmia the colour index is high, white cells and platelets are diminished, necrotic ulcerations occur, and there is no response to iron. If the spleen is enlarged the differentiation from splenic anæmia
- 2) may present much difficulty. In splenic anæmia the spleen is greatly enlarged, there is often a history of jaundice or hæmatemesis, the skin may be pigmented and the fingers clubbed, and there are signs of liver damage, such as enlarged veins, positive van den Bergh reaction and impaired lævulose tolerance. In the absence of such symptoms the patient should first be treated with large doses of iron, when both the anæmia and the splenic enlargement will disappear if the correct diagnosis is idiopathic hypochromic anæmia.
- 3)
- 4)

Course and Prognosis.—The disease is chronic, and the average duration of symptoms before treatment is 5 years. It is rarely fatal, but in the absence of proper treatment many patients remain invalids for years. There is a strong tendency to relapse, which can only be avoided by re-examination at intervals or by persisting with a small dose of iron.

Treatment.—Treatment is by large doses of iron by the mouth. Liver and stomach extracts are of no value in this disease. Transfusion is seldom necessary, and should be reserved for patients in extremis. Septic foci should be removed, especially from the mouth and pharynx. Factors likely to aggravate the anæmia, such as hæmorrhoids, should be dealt with appropriately. Hydrochloric acid relieves the dyspepsia, but has no action on the anæmia,

as it is impossible to give large enough doses to promote the absorption of iron from the food. Glossitis and dysphagia commonly improve when the anæmia is repaired; a simple mouth-wash may be prescribed, and Hurst's mercury tube may be passed for the dysphagia. Menorrhagia may be very troublesome; with rest in bed at the periods, large doses of calcium salts by mouth, and, if necessary, injections of cotarnine hydrochloride or hydrastinine hydrochloride, in younger subjects the condition usually subsides after a few months. After age 40 this complication is more intractable, and if it persists then, it may be advisable to induce an artificial menopause by means of X-Rays or operation.

4. PERNICIOUS ANÆMIA

Synonym.—Addison's Anæmia.

Definition.—A disease characterised by megalocytic anæmia, achylia, and a tendency to degeneration of the spinal cord, which pursues a remittent course, and which is invariably fatal unless appropriate treatment is instituted.

Ætiology.—The disease is most common between the ages of 40 and 60, though analysis shows that it becomes relatively more frequent in each decade. True pernicious anæmia has been observed in children, but it is very rare before the third decade. It is found in all civilised countries, though it is not very common in Jews. Males are probably more often affected than females, but on this point statistics disagree. There is a strong hereditary tendency, which appears to be due to inheritance of the basic factor, achlorhydia. As already mentioned, cases of achlorhydia without symptoms, achlorhydic dyspepsia, simple achlorhydic anæmia, pernicious anæmia and subacute combined degeneration are often observed in different members of the same family. Important predisposing factors which act by damaging the gastric mucosa, are gastritis, gastro-enteritis, dysentery and similar infections, and operations on the stomach. The relation of pernicious anæmia to pregnancy will be discussed later.

It is now believed that the gastric disease is the cause of pernicious anæmia, though the essential factor is not the absence of hydrochloric acid (achlorhydia), but of the gastric ferments (achylia). In normal gastric digestion substances are elaborated from the food by the proteolytic ferments of the gastric juice which are essential for the development of the megaloblasts of the bone-marrow into normoblasts and erythrocytes, and for the nutrition of the spinal cord. These substances are stored in the liver, and substitution therapy can be carried out in pernicious anæmia by the use of liver or gastric tissue from suitable animals. Pepsin and similar preparations, as it is only possible to demonstrate the full proteolytic activity of gastric ferments in fresh specimens of juice. In theory, these ferments might disappear from the gastric juice, and the secretion of hydrochloric acid be maintained; but in practice, this is an exceedingly rare event, and the diagnosis of pernicious anæmia in the presence of free acid in the gastric juice usually proves to be wrong.

Pernicious anæmia is a specific disease whose cardinal features have been defined as megalocytic anæmia, achylia, and a tendency to subacute combined degeneration of the spinal cord, and the diagnosis of pernicious

anæmia should be strictly confined to cases of this type. A similar type of megalocytic anæmia may occur in other diseases in which nutrition or digestion is impaired. These anæmias may be classified in the following two categories: first, megalocytic anæmia due to a defective diet, which does not contain the materials necessary for blood formation; and second, megalocytic anæmia due to diminished absorption of the hæmatinic principles, when the intestines are diseased. The gastric juice may be perfectly normal in such conditions, and there is rarely any tendency to subacute combined degeneration of the spinal cord. It is inaccurate and confusing to apply the name pernicious anæmia to all these conditions, though they are, of course, closely allied to pernicious anæmia in their symptoms and their pathology. They should be described as megalocytic anæmia and referred to their respective causes. Such a megalocytic anæmia may occur in the following diseases, but it is important for the student to recognise that it does not occur in every case of these diseases. Megalocytic anæmia rarely develops unless the disturbance of nutrition or of intestinal absorption is very profound.

(a) *Tropical nutritional anæmia*.—Megalocytic anæmia due to defective diet is uncommon in temperate zones except in fanatical vegetarians, but very common in tropical and sub-tropical countries where large populations subsist on famine diets. It is more common in women and often fatally aggravated by pregnancy. Effective treatment can be carried out not only by liver and similar preparations, but also by marmite, a yeast preparation which contains vitamin B and which has the advantages of being cheap and of not breaking caste regulations of diet.

(b) *Stenosis, resection or ulceration of the small intestine*.—These conditions probably act by interfering with absorption from the small intestine. Liver treatment is effective.

(c) *Intestinal parasites*.—The most important is Bothriocephalus latus. The mode of action is unknown, but is probably an interference with the absorption of the hæmatinic principles. Liver treatment is effective, but the specific treatment is expulsion of the parasite.

(d) *Sprue*.—Megalocytic anæmia is very frequent in sprue. It is in part due to the intestinal disease, but in the majority of cases the gastric secretion also is impaired.

(e) *Fatty diarrhœa*.—In fatty diarrhœa, such as occurs in coeliac disease, idiopathic steatorrhœa, pancreatic disease, gastro-colic fistula and after operations on the gastro-intestinal tract, megalocytic anæmia is occasionally observed, though not so constantly as in sprue. In the megalocytic anæmia of sprue and fatty diarrhœa, liver treatment is effective and marmite may also be effective.

Pathology.—The remainder of this section deals with true pernicious anæmia, though similar changes are observed in the other megalocytic anæmias just mentioned. The body may not be wasted, the fat is a peculiar yellowish colour and the muscles reddish-brown. All the tissues are anæmic, and the heart muscle shows fatty degeneration. Free iron is present in the liver, the kidneys and other tissues. The bone-marrow is hyperplastic, like red currant jelly, but usually there are some areas of aplasia; microscopic examination shows many megaloblasts, and in addition endothelial cells containing phagocytosed red cells and their debris. Degeneration of the

postero-lateral columns of the spinal cord is present in about 80 per cent. of cases. Owing to post-mortem changes, it has not yet been possible to determine the morbid histology of the changes in the gastro-intestinal tract.

Symptoms.—Patients with pernicious anæmia are not infrequently well built, with broad faces, short deep chests and wide sub-costal angles; the hair is often prematurely grey, and the skin may be pigmented. Its incidence in persons of this type was first noted by Addison, whose description of the symptoms remains unsurpassed. "The disease makes its approach in so slow and insidious a manner, that the patient can hardly fix a date to his earliest feeling of that languor which is shortly to become so extreme. The countenance gets pale, the whites of the eyes become pearly, the general frame flabby rather than wasted; the pulse perhaps large, but remarkably soft and compressible, and occasionally with a slight jerk, especially under the slightest excitement; there is an increasing indisposition to exertion, with an uncomfortable feeling of faintness or breathlessness on attempting it; the heart is readily made to palpitate; the whole surface of the body presents a blanched, smooth and waxy appearance; the lips, gums and tongue seem bloodless; the flabbiness of the solids increases; the appetite fails; extreme languor and faintness supervene, breathlessness and palpitations being produced by the most trifling exertion or emotion; some slight œdema is probably perceived about the ankles; the debility becomes extreme, the patient can no longer rise from his bed, the mind occasionally wanders, he falls into a prostrate and half-torpid state, and at length expires; nevertheless, to the very last and after a sickness of perhaps several months' duration, the bulkiness of the general frame and the amount of obesity often present a most striking contrast to the failure and exhaustion observable in every other respect."

Little can be added to this description of the anæmia except that the skin is often lemon yellow in colour, but overt jaundice is most unusual. The temperature may be slightly raised. Angina may occur, due to the impoverishment of the blood supplied to the heart. The spleen is palpable in about one-third of the cases, and the liver may be enlarged. The urine contains much urobilin and often a trace of albumin.

Alimentary symptoms constitute an important chapter of the disease. Glossitis of the type described in idiopathic hypochromic anæmia occurs in over 50 per cent. of cases, but curiously enough there is no tendency to involvement of the pharynx, or to dysphagia. It may precede the anæmia by some years. Achlorhydria is an invariable symptom, and pepsin is greatly reduced or absent. Achlorhydria has many times been demonstrated before the onset of the anæmia, and it persists when the blood has been repaired. Dyspepsia is frequently present, and there may be attacks of diarrhoea. The dyspepsia is partly due to the achlorhydria, but it is greatly aggravated by the anæmia, and in the critical periods of the disease vomiting may be so troublesome as to prevent effective medication by mouth. In other cases attacks of violent epigastric pain, with tenderness, rigidity and vomiting, occur at intervals, causing much alarm and difficulty in diagnosis because of their resemblance to an acute abdominal emergency. The attacks are probably of spinal origin and comparable with the gastric crises of locomotor-ataxia. Nervous symptoms, due to subacute combined degeneration of the spinal cord, are an integral part of the disease, and for

convenience they are described elsewhere (pp. 1714, 1715). Mental symptoms appear in a small percentage of cases; they are usually delusions of persecution, and the patient swears that he is being poisoned by his relatives or his physician. Exceptionally such patients become stuporose and die in coma, even though their anæmia is not profound.

The cardinal feature of the blood picture is megalocytosis. By the time the patient seeks medical advice the red cells are often less than 2 millions per c.mm., and counts of the order of half a million have occasionally been obtained. Hæmoglobin is not reduced to the same extent as the red corpuscles and the colour index is above unity. Such complications as hæmorrhage may lower the colour index, but megalocytosis persists. The mean diameter of the red cells averages about 8.3 microns; there is much anisocytosis and poikilocytosis. Reticulocytes are within normal limits except during a remission, spontaneous or induced. Normoblasts and megaloblasts are often present, more especially in the agonal stages of the disease and also on the inception of very active treatment; they are rarely present in mild cases, and their diagnostic importance has been greatly overestimated. The serum is brownish-yellow, and the indirect van den Bergh reaction is positive. The white cells are reduced in number, an average count being about 4000; the decrease is chiefly due to diminution in the granulocytes and the monocytes. The neutrophil cells are of an old type, many having 5 or more lobes to their nucleus, and occasional giant neutrophils and myelocytes are present. Platelets are scanty.

Complications and Sequelæ.—Complications are infrequent, for subacute combined degeneration is one of the elements of the disease and not truly a complication. It is doubtful whether pernicious anæmia ever terminates in aplastic anæmia, and most reports of this sequel can be attributed to errors of diagnosis or to incomplete examination of the marrow after death; arsenic may have produced aplasia of the marrow in rare cases before liver was introduced into treatment. Gout and venous thrombosis occasionally occur, especially during intensive treatment. There is suggestive evidence that patients with pernicious anæmia are abnormally prone to carcinoma of the stomach. Intercurrent infection, whether from diminished resistance on account of the anæmia, or from the trophic or bladder lesions of spinal paralysis, is a very dangerous event.

Course.—In young subjects the disease may run an acute course, with fever and purpura, and prove fatal after a short illness. Such a course is unusual, for remissions are one of the most constant features of the disease. The commonest number is two, but there may be five or six; their duration is about six months. The patient may feel perfectly well during a remission, but the blood rarely becomes quite normal. The untreated disease is usually fatal in one to three years, though exceptional cases may live much longer, usually as the result of an unusual remission. One of our patients at Guy's Hospital first came under treatment at age 30 for dyspepsia; at age 41 he was readmitted for typical pernicious anæmia, with high colour index and megaloblasts, which responded to treatment by arsenic; he remained well till age 64, when he was readmitted to hospital for relapse of the pernicious anæmia of ten months' duration; he had complete achlorhydria; the anæmia responded to treatment with liver. The cause of the remissions is uncertain, but is probably a partial recovery of the function of the stomach.

Diagnosis.—The disease is often suggested by the triad of symptoms, glossitis, anæmia and acroparæsthesia. It is confirmed by the blood picture, more especially the megalocytosis and anisocytosis, the absence of reticulocytosis, and the presence of hyperbilirubinæmia. In doubtful cases a test meal should be performed, for free hydrochloric acid in the gastric juice for all practical purposes rules out the diagnosis. The megalocytic anæmias of nutritional and alimentary disease which closely resemble pernicious anæmia have already been discussed. An important differential diagnosis is from carcinoma of the stomach. In this disease the faeces contain occult blood, and the anæmia is usually of a hypochromic type. In a few cases the two diseases co-exist, the pernicious anæmia being the result of a cancerous gastritis and achylia, or cancer developing in the stomach of a patient who already has pernicious anæmia. Aplastic anæmia may be mistaken for pernicious anæmia, but megalocytosis is absent, van den Bergh's reaction is negative, free hydrochloric acid is frequently present in the gastric juice and liver treatment is unsuccessful. The rare diseases aleukæmic leukæmia and chronic hæmolytic anæmia can usually be differentiated by careful analysis of the symptoms and the blood. In the absence of complicating infection, anæmia which does not respond to liver treatment in effective dosage is very unlikely to be pernicious anæmia.

Prognosis.—In exceptional cases the defective gastric function which produces pernicious anæmia is due to a recoverable gastritis, the gastric juice returns to normal and the patient is completely cured. As a general rule the disease is incurable, but with thorough and persistent treatment both the anæmia and the spinal symptoms can be completely arrested, and there is no reason why the patient should not live the normal

Treatment.—Treatment is by liver or stomach, as described at the end of the chapter. I cannot too strongly emphasise the necessity of keeping the blood at a level of 5 million red cells per c.mm., and 100 per cent. of hæmoglobin if nervous and infectious complications are to be avoided. Many patients have a delusive sense of well-being with a blood count as low as 3 million red cells per c.mm., and 60 per cent. hæmoglobin, but at this level the degeneration of the nervous system may continue to advance. It is, therefore, essential to examine the blood at regular intervals. Even with a normal blood count, acroparæsthesia or increase of the nervous symptoms demands a larger dosage of effective substance. After all, it is impossible to give an overdose. In later life absorption from the alimentary tract is sometimes diminished and very large doses of liver may be necessary, but desiccated stomach proves effective in relatively much smaller amounts. In difficult cases treatment by mouth should be supplemented by intramuscular injections of liver extract. In patients who are profoundly anæmic transfusion may be necessary, but in view of its dangers it should, wherever possible, be withheld in favour of injections of liver extract.

Hydrochloric acid may be advisable for the dyspeptic symptoms in patients treated by liver, but it is rarely necessary when desiccated stomach is used. Iron deficiency and hypothyroidism are occasional complications of pernicious anæmia. They should be suspected especially in patients in whom it is difficult to bring the blood completely back to normal, and they should be corrected by appropriate doses of iron or thyroid. Arsenic and intestinal antiseptics are to be avoided. Septic foci should be removed,

though the operation should be postponed until the anæmia is under control. Gastric lavage is a treatment whose possibilities have not yet been fully explored; it is probable that removal of septic foci from the mouth and throat, and regular lavage of the stomach, would restore the gastric secretion and thus completely cure the disease in a small percentage of cases, more especially those which follow a previous gastritis or gastro-enteritis.

The first phenomenon noted on instituting successful treatment in a patient with pernicious anæmia is an increased excretion of uric acid. This is due to the maturation of the nucleated red cells in the bone-marrow and the extrusion of their nuclei. After this there is a reticulocyte crisis, which reaches its maximum between the tenth and the fourteenth days, and is directly proportional to the severity of the anæmia; values of 30 to 40 per cent. are by no means uncommon. The blood and the general condition of the patient are gradually restored to normal, glossitis becomes quiescent, and the surface of the tongue may be reclothed with filiform papillæ. The nervous symptoms are slower to improve, and gross spastic paralysis is unlikely to be repaired. Nevertheless the degree of improvement may be surprising. In more than one bedridden case I have felt I was doing the patient little service in curing his anæmia, but after months of careful treatment, massage and re-education, the patient has successively discarded his wheel-chair, his crutches and his sticks, and has returned to active employment.

APLASTIC ANÆMIA

Definition.—Aplastic anæmia is produced by aplasia of the bone-marrow, which results in reduction or total failure of blood regeneration. Usually all three elements in the bone-marrow—erythropoietic tissue, leucopoietic tissue and megakaryocytes—are simultaneously involved. Rare cases occur in which there is a pure lesion of one of these tissues, and not infrequently one of them is predominantly affected. The term *aplastic anæmia* is applied more particularly to cases in which the erythropoietic tissue is especially damaged. Aplasia of the leucopoietic tissues is described later under the title *agranulocytosis*, and aplasia of the megakaryocytes under the title *malignant thrombocytopenia*.

Ætiology.—Rare as the disease is, its frequency has been underestimated because of its confusion with pernicious anæmia. Their only point of resemblance is the profundity of the anæmia, for the incidence, symptoms and pathology are entirely different. It occurs at all ages and in both sexes, but in my experience most frequently in males between the ages 20 and 40. In a number of cases the aplasia of the bone-marrow is due to destruction by a well-recognised poison of which the following examples have been recognised:

1. X-Rays, radium and thorium; radium is much more dangerous than X-Rays.
2. Benzol, arsenicals of the arseno-benzol group and T.N.T.
3. Acute infections, such as measles, scarlet fever, diphtheria and typhoid; these causes are more potent in childhood.
4. Extreme malnutrition, such as occurs in the late stages of sprue.
5. It has often been suggested that aplastic anæmia may develop as

a result of long continued anæmia and consequent exhaustion of the bone-marrow. In my opinion, however, there are no facts to support this suggestion. In the conditions in which the erythropoietic tissues are most persistently exercised, such as repeated hæmorrhage, or the life-long hæmolysis of acholuric jaundice, aplasia of the bone-marrow is unknown. There is no relation between aplastic anæmia and pernicious anæmia. In pernicious anæmia certain portions of the bone-marrow, notably the distal extremities of some of the long bones, may undergo aplasia, but in such cases the erythropoietic function of the bone-marrow as a whole still remains increased.

The above groups of cases may be described as secondary aplastic anæmia. In a larger proportion of cases no noxious agency can be traced and they are therefore described as primary aplastic anæmia. It is possible that there is a constitutional predisposition to the disease, and this is particularly suggested by the very small percentage of cases in which aplastic anæmia develops after the injection of salvarsan; all are exposed to the same poison, but in only a few does the bone-marrow succumb.

Pathology.—Pathologically the features are profound anæmia, generalised hæmorrhages, and a fatty atrophic bone-marrow. Careful examination nearly always reveals evidence of a certain amount of marrow regeneration, in the form of small islands of hæmopoietic tissue in the midst of the fatty and aplastic marrow. Necrotic ulcers are commonly found in the mouth and more rarely in the bowel. The liver, spleen and lymph-glands show no gross change, but microscopically there is usually some hæmosiderosis of the liver and spleen, attributable both to the absorption of extravasated blood and to the breakdown of transfused red cells.

Symptoms.—The disease usually begins insidiously with malaise, anorexia and the symptoms of anæmia; but in one of my cases which subsequently came to autopsy the onset was abrupt with jaundice and high fever. Other initial symptoms are hæmorrhage, from an associated thrombocytopenia, and necrotic ulcerations due to the leucopenia. The pallor is often profound, and yet it is surprising how well the patient may feel until the onset of air hunger or œdema marks the beginning of the end. The mind is almost distressingly clear, though delirium may develop before death, perhaps as the result of multiple punctate cerebral hæmorrhages. There is usually low-grade fever, which may terminate in hyperpyrexia. Any dyspeptic symptoms present can be attributed to the anæmia, the tongue is normal, and the gastric secretion unaffected.

Physical examination is commonly negative, except for the anæmia and such complications as purpura and ulceration. The weight is maintained, but the blood pressure may fall very low. Subacute combined degeneration of the spinal cord does not occur. The liver is not enlarged and the spleen is not palpable, unless there are complications, such as infarctions. Death finally results from anæmia, hæmorrhage, or infection. The average duration of collected cases is eight months, though it is more typical for death to occur about three months after the onset of symptoms. Fulminating cases may die in a few days, usually from exsanguination by hæmorrhage. Exceptionally life has been prolonged for five years.

By the time a blood count is done, the red cells have usually fallen to about 1·5 million per c.mm. and the colour index is about unity. The white cells are about 3000 or 4000 per c.mm., usually falling below 2000 before

death; the diminution is chiefly due to the small number of polymorpho-nuclear cells. Blood platelets are similarly reduced. The size of the red cells may be slightly increased, but there is little anisocytosis. Reticulocytes are commonly below 1 per cent., and there are no nucleated red cells; as a result probably of the efforts of the surviving remnant of erythropoietic tissue to repair the anæmia, reticulocytes may rarely rise to 4 or 5 per cent., and an occasional normoblast may appear. Van den Bergh's reaction is negative.

Diagnosis.—Careful investigation will soon exclude pernicious anæmia. Essential thrombocytopenia may be suggested by the low platelet count and the hæmorrhagic tendency, but it is excluded by the leucopenia and the non-regenerative character of the anæmia. Aleukæmic leukaemia offers most difficulty, but the absence of enlargement of the lymph-glands, liver, or spleen should differentiate aplastic anæmia from this disease.

Prognosis and Treatment.—The outlook is almost hopeless, but recovery occasionally occurs in childhood and in secondary aplastic anæmia when the cause has been removed. Iron and liver will usually be tried, and there may be a delusive transient improvement, but in general they have little effect. Adrenaline, in a daily dosage of 5 minims subcutaneously, has been recommended. Transfusion is the sheet-anchor in treatment. The physician should endeavour to bring the blood approximately to normal by a rapid series of transfusions. It may then be possible to maintain a normal count by a fortnightly transfusion, and there is a hope that after an interval of months or years the bone-marrow may regain its hæmopoietic function. Too often it is found that the transfused blood is quickly and mysteriously destroyed, and in such cases the physician is at the end of his resources.

THE HÆMOLYTIC ANÆMIAS

Less importance than formerly is attributed to hæmolysis in the genesis of anæmia, for careful investigations have shown that it is not often an ætiological factor. In discussing the symptomatic anæmias, I have mentioned the occasional development of anæmia from hæmolysis of the corpuscles by micro-organisms, bacterial toxins and other poisons. There now remains for discussion a group of hæmolytic anæmias which are relatively uncommon and of which the most important examples, acholuric jaundice, sickle-cell anæmia and the grave familial jaundice of infants, are due to congenital anomalies in the blood-forming organs. Before treating these diseases individually, it will be convenient to describe the characteristics which are common to all the hæmolytic anæmias. If a great many red cells are broken down in a short time, there are hæmoglobinuria and jaundice, but in chronic hæmolytic anæmia it is sometimes surprising how slight is the jaundice. The colour index varies according to the mode of reaction of the bone-marrow, but it is usually round about unity and there may be frank megalocytosis. Owing to the vigorous attempts of the bone-marrow to repair the anæmia, the reticulocyte count is high, and nucleated red cells and even megaloblasts appear in the peripheral blood. The fragility of the red cells varies in different individuals, and at different times in the same individual. The resistance to hypotonic saline may be diminished in acquired hæmolytic anæmia, and

it may be normal in congenital acholuric jaundice. In chronic hæmolytic anæmia the white cells are unaffected or a little diminished. When hæmolysis is acute and rapid, there is a leucocytosis, during which very immature white cells may appear in the peripheral blood; the platelets first fall and later rise above their normal level. Apart from the hæmolysis, which gives rise to anæmia, enlargement of the liver, spleen, and occasionally the lymph-glands, hyperplasia of the bone-marrow and hæmosiderosis, there are no signs of systemic disease and the alimentary and nervous systems are normal.

1. ACHOLURIC JAUNDICE

Synonyms.—Spherocytosis; Congenital Hæmolytic Anæmia.

This disease which is due to congenital abnormality of the red corpuscles, and is characterised by increased fragility of the cells, a variable degree of jaundice and anæmia, splenomegaly, and a strong tendency to the formation of gall-stones, is described elsewhere (page 667).

2. SICKLE-CELLED ANÆMIA

Synonym.—Drepanocytosis.

Definition.—A severe anæmia, characterised by the appearance in the blood of a number of red blood corpuscles of a peculiar sickle shape.

Ætiology and Pathology.—Up to the present the disease has been observed only in the negro. It is hereditary and familial, behaving as a Mendelian dominant. In the affected families some members who have sickle cells in their blood do not suffer from anæmia. The disease usually dates from infancy. Of its essential cause, nothing is known. The post-mortem appearances do not throw any light upon the pathology.

Symptoms.—The patients are obviously anæmic, and the sclerotics exhibit a greenish-yellow tinge. The liver is bulky, but the spleen is not enlarged. The disease is characterised by intermittent paroxysms of fever, up to 103 or 104 degrees, with severe stabbing pains in the muscles and joints, which last for two or three weeks. In the intervals the patients suffer but little, though they are listless and depressed. The red blood corpuscles in the intervals reach a number of about 3,000,000 per c.mm., but during the paroxysms they rapidly fall to less than half that number. The white cells are usually about 15,000 per c.mm., but may rise to as much as 40,000. The sickle-shaped corpuscles vary in numbers. They appear to increase in number on a warm slide. The coagulation-time, the bleeding-time, the fragility of the corpuscles, and the numbers of platelets are all within normal limits.

Course and Prognosis.—The course of the disease is slow but progressive, and death usually occurs before the age of thirty.

Treatment.—Up to the present time, no treatment has appeared materially to influence the progress of the disease, and splenectomy is of no value.

3. OVALOCYTOSIS

In rare cases the red cells are elliptical, instead of being circular. This again is a familial abnormality, inherited as a Mendelian dominant, but it is not certain that it predisposes to anæmia.

4. FAMILIAL ICTERUS GRAVIS NEONATORUM

This is a familial disease in which successive infants in the same family become jaundiced within a few hours to a day after birth, though the first-born often escapes. They become progressively anæmic, pass into a drowsy condition, and usually die in a few days or weeks. At its onset the disease resembles physiological jaundice and, like it, it does not show any gross post-mortem appearances to account for the jaundice. During intra-uterine life the red cells circulate in higher concentration than after birth, to compensate for the poor supply of oxygen from the placenta. It is probable that physiological jaundice results from the hæmolysis of superfluous corpuscles on the inception of pulmonary respiration, and that grave familial jaundice is a morbid exaggeration of this process. Affected children nearly always died until Hampson showed that they could be cured by the injection of 5 to 10 c.cm. of the mother's blood serum daily into the infant's muscles.

5. ACUTE HÆMOLYTIC ANÆMIA OF LEDERER

Synonym.—Acute Febrile Anæmia.

Acute anæmias of a hæmolytic type are occasionally seen, more especially in the first two decades of life, for which no adequate explanation can be found. The temperature is raised, and the clinical picture is that of an acute systemic infection, but blood cultures and examination of the tissues for micro-organisms are negative. In the most acute cases hæmoglobinuria is present. In other cases there is a great leucocytosis and white cells of the most immature type may be apparent in the circulating blood, so that it is difficult to differentiate the condition from leukæmia (see p. 791). The disease ends either in death or complete recovery within a few weeks. Treatment by transfusion is often dramatically successful.

6. CHRONIC ACQUIRED HÆMOLYTIC ANÆMIA

Synonyms.—Hæmolytic Anæmia (type Hayem-Widal).

Chronic acquired hæmolytic anæmia resembles acholuric jaundice, except that there is no family history of the disease. There is persistent hæmolysis, with slight jaundice, anæmia, reticulocytosis and usually splenomegaly. It is much rarer than acholuric jaundice, and wherever possible its acquired character should be confirmed by examination of the parents or other relatives, as patients are so often ignorant of their true state of health. Careful examination of the blood also reveals differences from acholuric jaundice. The shape of the red corpuscles is normal, and the resistance to hypotonic saline solution is not always affected. The clinical course of the disease is much more severe than acholuric jaundice, and death usually occurs within a few years. Hæmolytic crises are more frequent, and paroxysmal hæmoglobinuria occurs even in non-syphilitic cases. It is a syndrome rather than a disease entity, and it may be produced by a variety of causes, of which the most important are syphilis, Hodgkin's disease, cirrhosis of the liver, and splenic anæmia, though it is, of course, a rare symptom in any of these diseases. In a few cases no primary pathological lesion can be demonstrated. Good results are reported from treatment with salvarsan in cases

due to syphilis. If the spleen is enlarged, improvement may follow its removal, though this cannot be promised with the same confidence as in cases of acholuric jaundice. Liver is ineffective, and transfusion is very dangerous, as it is often followed by a hæmolytic crisis.

ANÆMIA IN PREGNANCY

It is customary to describe a *physiological anæmia of pregnancy*, but the term is rather a misnomer, for although the blood is slightly diluted in pregnancy, the hæmoglobin does not fall below 75 per cent. in healthy women. There seems to be no form of anæmia in which pregnancy has not occurred in some instance, and a pre-existent anæmia is always aggravated by pregnancy. Pregnancy is, in fact, a very undesirable complication in such diseases as acholuric jaundice and splenic anæmia. The commonest form of anæmia in pregnancy is a hypochromic anæmia, often called the *chlorotic anæmia of pregnancy*. This is another misnomer, as chlorosis should be benefited by pregnancy, and further investigation has shown that these are cases of simple achlorhydric or allied anæmia aggravated by pregnancy; achlorhydria is present in 80 per cent. of the cases, and the anæmia responds to massive dosage with iron. Megalocytic or hyperchromic anæmia is very rare in pregnant women in this country, though it is common in tropical or sub-tropical zones. The condition may have different causes, and the prognosis differs accordingly. The following causes of megalocytic anæmia in pregnancy have been differentiated.

1. *Tropical nutritional anæmia* is much aggravated by pregnancy, and then assumes a frankly megalocytic type.

2. Pregnancy may occur in a patient with *pernicious anæmia*, or pernicious anæmia may first begin in pregnancy, persisting after gestation; achylia gastrica is present, and subacute combined degeneration may develop.

3. Pernicious anæmia may occur as a temporary phenomenon during pregnancy, disappearing after gestation. The secretion of free hydrochloric acid may be normal, but there is evidence that the hæmatinic ferments are depressed, presumably as a result of the pregnancy. Subacute combined degeneration does not occur. The disease responds well to treatment by liver or stomach. It may or may not recur in subsequent pregnancies. This is the true *pernicious anæmia of pregnancy*, and it is very rare.

Hæmolytic anæmias, which should be separable from pernicious and allied anæmias by the Price-Jones curve and the reticulocytosis, also occur in pregnancy. Most frequently they result from infection by hæmolytic streptococci in the puerperium. It is also probable that the hæmolytic anæmia of Lederer occurs in pregnancy.

ANÆMIA IN CHILDHOOD

Anæmia in children is more difficult to classify than in adults, not merely because of the difficulty of making detailed studies of the blood and the other systems, but also because of the great lability of the blood-forming organs of children. A condition which in an adult induces a mild secondary anæmia, with slight leucocytosis and perhaps an occasional normoblast, in a child

induces profound anæmia, with the appearance of myelocytes and even myeloblasts and megaloblasts in the circulating blood; the spleen and the liver are more often enlarged. Both on this account and on account also of the small blood volume, anæmia is a more urgent disease in the child than in the adult; hæmorrhage is ill-tolerated, and a moderate nutritional anæmia may be fatally aggravated by a trivial intercurrent infection. Treatment should therefore be prompt, and it is often wise to give a transfusion of 50 to 200 c.cm. of blood to tide over the interval before medical treatment can take effect. For similar reasons the results of treatment are often better in the child than the adult, and aplastic conditions of the bone-marrow which are almost inevitably fatal in the adult may be repaired in the child. Apart from certain rare congenital anæmias, the causes of anæmia in childhood are identical with those in later life, and with careful clinical and hæmatological examination, supplemented if necessary by the van den Bergh reaction, the fragility test and the Price-Jones curve, a satisfactory diagnosis should usually be obtained. In this way the vague titles formerly used, such as anæmia mitis and gravis, and pseudo-leukæmia, are gradually being replaced as the result of more exact diagnoses.

Symptomatic Anæmia is little different from the same condition in the adult. Hæmorrhagic anæmia is rather unusual in childhood, while causes more peculiar to this age are cyclical vomiting, diphtheria, pyelitis and acute rheumatism. Anæmia may also be secondary to diseases of the blood-forming organs, such as splenic anæmia and Hodgkin's disease. Any type of anæmia in childhood may be complicated by infection, when very bizarre leukæmoid blood pictures may result.

Anhæmopoietic Anæmia.—There is a group of mild hypochromic anæmias in childhood which link the nutritional anæmia of infancy with the simple achlorhydric anæmia and allied anæmias of later life. The condition has been described as *anæmia mitis* or *chlorotic anæmia of childhood*, but it is essentially due to errors of diet and impaired digestion. Treatment is by large doses of iron, and is very successful. Severe anæmia may occur in the course of coeliac disease, and in occasional instances it is of a megalocytic type and requires liver for its treatment; the anæmia may dominate the clinical picture and the fatty diarrhoea be overlooked. True pernicious anæmia also occurs in childhood, but it is very rare, and the diagnosis needs confirmation by the fractional test meal, the van den Bergh reaction and the Price-Jones curve.

Aplastic Anæmia is by no means uncommon in childhood, occurring with special frequency at the age of 12 or 13. It may be of any of the types described in the adult, and is sometimes known as *anæmia gravis*. The prognosis is bad, though perhaps less hopeless than in the adult.

Hæmolytic Anæmias are probably more common in the child than the adult. Familial icterus gravis neonatorum and acholuric jaundice have already been described, but there is a third rare hæmolytic anæmia, of congenital origin, which is known as the *erythroblastic anæmia of childhood*. It is characterised by slowly progressive anæmia, with large numbers of nucleated red cells in the peripheral blood, enlarged spleen, mongoloid facies and distinctive changes in the bones due to marrow hyperplasia. It is apparently limited to the Mediterranean races, and in the majority of instances is fatal within a few months or years. Hæmolytic anæmia in

childhood may also be due to infection. Cases characterised by the rapid development of anæmia, jaundice and hæmoglobinuria at one time appeared in epidemics among new-born children in hospitals and institutions (Winckel's disease), but they have practically disappeared with the introduction of antiseptic methods. They were probably due to infection by streptococci or hæmolytic colon bacilli, and sporadic cases still occur as a result of umbilical sepsis. In infancy and later childhood acute hæmolytic anæmias are described which appear to be examples of the acute hæmolytic anæmia of Lederer, and which respond in a dramatic manner to transfusion.

POLYCYTHÆMIA

Polycythæmia is a condition in which there is an increased number of erythrocytes per unit of circulating blood. It may be due to known causes, when it is called secondary polycythæmia, or *erythrocytosis*; or it may be an independent disease of the blood-forming organs, when it is called polycythæmia vera, or *erythramia*. The following causes of erythrocytosis are known:

1. Concentration of the circulating blood, such as occurs in the dehydration of choleraic diarrhœa.

2. Diminution of the oxygen tension in the circulating blood or tissues. Examples of this are—(a) residence at high altitudes; (b) cardiac diseases with cyanosis, especially congenital pulmonary stenosis and acquired sclerosis of the pulmonary arteries (Ayerza's disease, or *cardiacos negros*); (c) conditions interfering with normal pulmonary ventilation, such as emphysema, asthma, fibrosis and neoplasms of the lungs.

3. Chronic poisoning by a number of chemical agents, such as arsenic, phosphorus, carbon monoxide and aniline derivatives.

4. Cirrhosis of the liver and similar conditions associated with splenomegaly or portal stasis, in rare instances.

5. A transient erythrocytosis may occur in the stage of recovery from anæmia.

These causes should always be excluded before diagnosing polycythæmia vera.

1. POLYCYTHÆMIA VERA.

Synonyms.—Erythramia; Splenomegalic Polycythæmia; Osler-Vaquez Disease.

Definition.—A disease characterised by well-marked and persistent increase in the number of red corpuscles due to an excessive erythroblastic activity of the bone-marrow, which appears to be the primary factor in the condition.

Ætiology.—Cases of erythramia rarely come under observation before middle or later life, and we do not know how long the disease is present before symptoms are produced. It affects both sexes, but in my experience males more commonly than females. Occasionally several members of the same family are afflicted. The disease appears to begin as a hyperplasia of the erythropoietic tissue of the bone-marrow of unknown causation, and the erythrocytosis and splenomegaly are secondary to the disease of the marrow.

Pathology.—The marrow of most of the shafts of the long bones is converted into active red marrow. The spleen is enlarged and engorged, and often contains thrombotic infarcts. The liver is congested, but no anatomical change is present in it.

Symptoms.—Early symptoms are nervousness, headache, digestive disturbances and hæmorrhage from the distended vessels. The nervous symptoms take the form of lack of concentration, headaches, vertigo, or paræsthesiæ, on account of which the patient may be regarded as suffering from neurasthenia or hyperpiesia. Sometimes temporary disturbances of vision, aphasia or paralyzes occur, which recover completely in a few hours. The patients are usually spare, with fair complexion and thin, often narrow, faces. There is cyanosis of the exposed surfaces, especially the cheeks, the tip of the nose and the ears. The colour varies with the temperature, being scarlet in a warm atmosphere and dark blue in the cold. The eyeballs are often bloodshot, the conjunctivæ deep red, the retinal vessels engorged and tortuous, the discs a little swollen. The spleen is palpable in three-quarters of the cases; it rarely extends beyond the umbilicus and varies in size, shrinking after a hæmorrhage or successful treatment. The liver is palpable in about one-half the cases. The urine may contain a little albumin. The blood contains from 7 to 14 million red corpuscles per c.mm., and the hæmoglobin may reach 200 per cent. The red cells are usually smaller than normal, and the colour index is less than unity. The white cells are normal or moderately increased by a polymorphonuclear leucocytosis. In a few cases many myelocytes appear, as if there were a combination of erythræmia and leukæmia (erythro-leukæmia). The reticulocytes and the platelets are normal.

Complications.—The most important complications are vascular, and result from the increased volume and viscosity of the blood and its sluggish flow. It is noteworthy, however, that hypertension is no more common than in normal individuals in the same age-groups. Not uncommonly there are massive hæmorrhages, especially from the stomach, but also from the nose, lungs, bowel, uterus and bladder, or internally. Thrombosis is not infrequent, and in the cerebral vessels or the portal vein its consequences may be grave. It is rare for a case to progress any length of time without symptoms of peripheral arterial disease. In the beginning these take the form of acro-paræsthesia and vasomotor disturbances of a dilator (erythromelalgia), or spastic type (Raynaud's syndrome). Later, intermittent claudication and gangrene may follow.

Course and Prognosis.—The disease is very chronic, and sometimes it may exhibit long remissions. Life may be cut short by one of the vascular accidents or by infection, but many cases live to an advanced age.

Treatment.—Treatment is symptomatic. Relief is sometimes obtained by regular venesection, but its effects are very temporary. I have seen most benefit from the application of X-Rays to the long bones; the blood count is reduced to normal and there is a long remission of symptoms, after which the treatment can be repeated. If X-Ray treatment is not available, phenylhydrazine may be used to destroy the excess of blood, but it should be remembered that many patients have been made dangerously ill and some have died as a result of the incautious administration of this drug. It should rarely be given in a higher dosage than 2 grains a day (by mouth), and treat-

ment should be guided by frequent blood examinations. The drug has a cumulative action, and the red cell count may continue falling rapidly for 2 or 3 weeks after administration of the drug has been stopped, so that the patient dies of anæmia. Nausea, vomiting, jaundice, thrombosis, and necrosis of the liver and the kidneys have also been observed. It is therefore most important to begin with a small dose, and to interrupt the treatment and watch its effect as soon as the red cells begin to diminish. In this way it is possible to find a dose which will maintain a normal blood count, and frequently 2 grains a week is sufficient. Treatment with oxygen and with spleen extracts is ineffective, and splenectomy is contra-indicated.

2. ENTEROGENOUS CYANOSIS.

Synonyms.—Methæmoglobinæmia ; Sulphæmoglobinæmia.

Definition.—A rare disease characterised by chronic cyanosis, without cardiac or pulmonary lesions, and by the presence of methæmoglobin or sulphæmoglobin in the circulating blood.

Ætiology.—In the great majority of cases the condition is due to the use of drugs, especially aniline derivatives—phenacetin, acetanilide, trional, sulphonal, potassium chlorate, nitrites, etc. Methæmoglobinæmia, which is produced by the direct action of the chemical on the red cells, is much less common than sulphæmoglobinæmia. In sulphæmoglobinæmia the chemical sensitises the red cells, so that the hæmoglobin combines with hydrogen sulphide absorbed from the intestine. Sulphæmoglobinæmia is therefore much more likely to develop in constipated patients. The usual sequence of events is: constipation; headache; the use of headache powders which contain phenacetin or acetanilide; enterogenous cyanosis. The condition is more common in women than men, and in many instances it is deliberately perpetuated by the patient as a form of hysteria or malingering. In a few cases there is no evidence of the use of drugs, and in some of these cases disease of the bowel has been present.

Symptoms.—The patient complains of weakness, nervousness, vertigo or fainting attacks, palpitation, headache and constipation. The degree of cyanosis varies from a slight muddiness of the complexion to a deep blue. In marked cases the appearance of the patient is indeed ghastly, and yet it is belied by the comfortable general condition, the absence of any respiratory distress and the extreme rarity of a fatal issue. The blood may show a slight polycythæmia.

Diagnosis and Treatment.—The diagnosis depends on the spectroscopic examination of the blood for methæmoglobin or sulphæmoglobin. The use of drugs should always be suspected, especially in chronic and apparently inexplicable cases in women. It is surprising how skilfully they deceive their attendants and escape detection. I have known more than one woman who has lived many months in hospital and has been shown at medical meetings as a rare and mysterious case when all the time the symptoms were being produced by a bottle of phenacetin tablets concealed in the locker. Recovery occurs spontaneously when the drug is discontinued. In unexplained cases improvement may be brought about by irrigation of the colon with dilute solutions of potassium permanganate.

THE WHITE BLOOD CELLS

The white cells of the blood can be divided into three main groups : the granular leucocytes or granulocytes, the lymphocytes, and the large mononuclear cells or monocytes. The *granulocytes* have nuclei which are arranged in 2, 3 or 4 or more lobes, and are subdivided by the character of their protoplasmic granules into neutrophil, eosinophil and basophil polymorphonuclear cells. They are formed in the bone-marrow from non-granular cells with a round nucleus and basophil cytoplasm known as myeloblasts. As the cells mature they first develop granules when they are known as myelocytes, and later the nucleus takes on the lobed appearance of the adult polymorphonuclear cell.

The *lymphocytes* are sometimes subdivided into small, intermediate and large, but this subdivision has no practical value as long as the large lymphocytes are counted as lymphocytes and not erroneously included with the large mononuclear cells or monocytes. The lymphocytes are clearly distinguishable in stained preparations by their purplish blue nucleus, which is made up of large, deeply stained chromatin masses, and is round, oval or slightly indented. The cytoplasm is only a narrow rim in the small lymphocyte, but it forms a broad zone in the large lymphocyte, paler round the nucleus. It is of a clear sky-blue colour and may contain a few bright red granules (azur-granules). The lymphocytes develop in the follicles of the lymph-glands and other lymphatic structures of the body, the primitive cells from which they arise being known as lymphoblasts.

The *monocytes*, which are also known as large mononuclears, large hyalines, transitionals, endothelial leucocytes or splenocytes, are the largest cells in the blood. Their cytoplasm is of a greyish or powder-blue colour, owing to the presence of abundant dust-like granules. The nucleus is large, excentric, and round, notched, horse-shoe, or even convoluted in shape ; it is pale bluish-violet in colour, and the chromatin is fine and reticulated. The monocytes are differentiated from the lymphocytes by their powder-blue cytoplasm and reticular nucleus, and from the myelocytes by the fineness of their granulation. The monocytes are closely related to the phagocytic cells or histiocytes which are present in all the mesoblastic tissues and are concentrated in the sinuses of the liver, the spleen and the bone-marrow, a group of cells now known as the reticulo-endothelial system. The monocytes are formed chiefly in the connective tissues, the lymph-glands and the spleen.

All the normal white cells of the blood are actively motile. The immature cells from which they arise are not motile, and in health it is only when the cells become mature that they are able to migrate into the blood stream. It is sometimes difficult or impossible to decide the true nature of the immature non-granular white cells which appear in the blood in disease, though assistance may be derived from the clinical symptoms and the complete blood picture ; it is rarely a matter of much clinical importance, as long as they are recognised to be primitive cells.

It is important to be familiar with the normal fluctuations of the white cells. In healthy individuals the total number of white cells may vary from 3500 to 12,500 per c.mm., the average being 7500. A typical differential count is : neutrophils 66 per cent., eosinophils 2·5 per cent., basophils 0·5 per

cent., lymphocytes 24 per cent., monocytes 7 per cent.; but there are great physiological variations which are best illustrated by the absolute values of the different cells. The total number of neutrophils may vary from about 1500 to 10,000; eosinophils from 0 to 1000; basophils from 0 to 500; lymphocytes from 600 to 4000; and monocytes from 0 to 1750. The total white count is at a minimum or basal level when the subject is at rest in the morning; activity, mental or physical, increases it by 60 or 100 per cent.; in addition there are rhythmical fluctuations in the number of polymorphonuclears, lymphocytes and monocytes, which are probably associated with the replacement of dead or emigrated cells. It is unwise to draw far-reaching conclusions from a single count of the white cells, and the test should always be repeated when an anomalous result is obtained, or when it is uncertain whether the figures fall within normal limits.

LEUCOCYTOSIS

The white cells are not known to have any physiological function, their rôle being confined to the protection of the body from attack and invasion by bacteria or similar agencies. They may be compared with a standing army which performs no useful service in times of peace, but which possesses great reserves which may be mobilised in time of war. We might press the analogy further and compare the three main groups of blood cells, the granulocytes, the lymphocytes and the monocytes, with the different fighting branches, for just as different types of warfare require different arms, so the three main groups of blood cells show independent variations in the various phases of an infection, and respond differently to different kinds of disease. An increase in the neutrophil leucocytes should strictly be called neutrophil leucocytosis or neutrophilia, but when the term leucocytosis is used without qualification it is taken to mean a neutrophil leucocytosis. Leucocytosis occurs physiologically during the later stages of pregnancy and for about a week after delivery; in the newly born infant; and after exercise, as many as 35,000 cells per c.mm. having been found after violent exertion. The causes of pathological leucocytosis are:

1. Hæmorrhage, or trauma in which tissues are injured and blood is extravasated.
2. Acute infections, especially by the pyogenic cocci.
3. Acute intoxications, such as diabetic coma, uræmia, gout, lead colic, coal-gas poisoning, and poisoning by a number of organic and inorganic substances.
4. Malignant disease, especially when the tumour grows rapidly, or involves the alimentary tract or the bone-marrow, and some cases of Hodgkin's disease.

The number of white cells in these conditions commonly varies from 12,000 to 40,000 per c.mm., according to the acuteness of the infection or intoxication, and the patient's ability to respond; in exceptional cases the count may even exceed 100,000. The neutrophils are less mature than normal, or are altered by the toxæmia, so that many of the cells have only one or two lobes to their nuclei—a phenomenon described as the "shift to the left." In profound infections in which the patient's resistance is over-

come there may be no increase in the total number of white cells, but a considerable shift to the left is present; this is a sign of very ill omen.

When there is a considerable leucocytosis, myelocytes may appear in the peripheral blood. Small numbers of these cells are not infrequently found in pneumonia and scarlet fever. In exceptional circumstances large numbers of myelocytes may appear, sometimes accompanied by the more primitive non-granular myeloblasts. Such cases are important because of the difficulty of diagnosis from myeloid leukæmia. These *leukæmoid* blood pictures are more common in children, because their hæmopoietic tissues are less stable than the adult, and it is a good clinical axiom never to give a completely hopeless prognosis in apparent leukæmia in a child or a pregnant woman. There must also be a constitutional difference in the leucopoietic tissues, so that certain individuals are prone to produce immature white cells in circumstances in which others would respond with a normal leucocytosis. This is well exemplified by Downey's observation of a mother and her two children who all three developed a blood picture like that of myeloid leukæmia as a result of mercurial poisoning, but recovered completely; mercury does not have this action on ordinary individuals. The chief conditions in which the blood picture may at times simulate myeloid leukæmia are severe infections, miliary tuberculosis, Hodgkin's disease, malignant growths, and diseases of the bones; of course anæmia is present at the same time. It may be difficult to decide whether a case is primarily an infection with an abnormal white cell response, or whether it is not really leukæmia with intercurrent infection. Leukæmia may be closely simulated by the following conditions:—

1. ANÆMIA PSEUDO-LEUKÆMICA INFANTUM.

This term was applied by von Jaksch to a group of cases of severe anæmia in children under 3 years of age, most frequent between 6 and 20 months. It is a disease of the poorer classes, and among them it has become uncommon in recent years. The onset of the disease is insidious, with increasing pallor and irregular fever. The abdomen is protuberant, owing to the size of the spleen, which often reaches the iliac crest and the middle line of the belly; the organ is hard, smooth and free from tenderness. The liver and the superficial lymph-glands may be slightly enlarged, and purpura and hæmorrhages may occur. The erythrocytes are diminished to 2,500,000 or 3,000,000, per c.mm., and show some slight alteration in shape and size. Nucleated cells are always present—sometimes in large numbers. The hæmoglobin shows a decrease to from 20 to 40 per cent. of the normal, so that the colour index is low, from 0.5 to 0.7. There is nearly always a leucocytosis at some time during the course of the disease, but it is moderate, rarely reaching above 30,000, and sometimes the number may sink as low as 5000. The feature of the blood film is the constant presence of myelocytes, which occur in numbers greatly above those found in any other disease except leukæmia, though seldom in numbers sufficient to suggest that disease. Not infrequently there is evidence of excessive blood destruction.

It is now held that the syndrome described by von Jaksch is not a single disease entity, but that it includes various types of anæmia of nutritional or infectious origin, modified by the peculiar lability of the blood-forming

organs in childhood. Other cases so diagnosed are really examples of pernicious anæmia, acholuric jaundice, splenic anæmia, and similar diseases manifesting themselves at an early age. In the majority of cases the prognosis is good, the anæmia is completely repaired, and the spleen can no longer be palpated. Death may, however, occur from intercurrent maladies such as acute diarrhoea or broncho-pneumonia. It is obviously important to remove the cause when this can be ascertained, and malnutrition, rickets, tuberculosis and syphilis should receive their appropriate treatment. Transfusion is indicated when the anæmia is severe, and iron and liver are usually of great service. For the rest, every effort should be made to improve the diet and the general hygienic conditions. The patients do best with abundance of fresh air and light, and if possible should be nursed in the open air. Splenectomy is contra-indicated.

2. SEPTIC AND INFECTIOUS ANÆMIA.

When the blood is flooded with hæmolytic organisms, such as the streptococci, hæmolytic staphylococci, *B. welchii* or *Bartonella*, large numbers of red cells may be suddenly destroyed, and the bone-marrow responds with a great outpouring of nucleated red cells, myelocytes and even myeloblasts. This event is especially likely to occur in puerperal infection and in severe gas-gangrene. It is a curious fact that the same clinical picture of severe systemic infection and the appearance of immature red and white cells in the blood may sometimes be observed, especially in the first and second decades of life, and yet the pathologist is unable to isolate any known organism from the blood or tissues (see Acute Hæmolytic Anæmia of Lederer, p. 776). The mortality of untreated cases is high, but with transfusion some of these obscure and uncommon cases get better. It is legitimate to believe that they are acute leukæmia with recovery, but it is more probable that they constitute a group of infectious anæmias of unknown ætiology.

3. MARBLE BONES.

Synonyms.—Albers-Schonberg Disease; Osteo-Petrosis; Congenital Osteosclerotic Anæmia.

This is a rare congenital disease, sometimes affecting several children in a family, in which the bones become solid, owing to the obliteration of the medullary cavities by a centripetal thickening of the bone cortex. The liver and spleen hypertrophy, and take over the hæmopoietic functions of the marrow. Compensation may be perfect, but in other cases severe anæmia develops and nucleated red cells and myelocytes appear in the peripheral blood. The disease is sometimes present at birth, but in other cases it only becomes manifest in adolescence or later life. Owing to the inelasticity of the bones spontaneous fractures may occur. There is no treatment, but it is important to remember that the hyperplasia of the spleen is compensatory, and that splenectomy or the application of X-Rays can only do harm.

4. METASTATIC TUMOURS OF BONE.

Synonym.—Secondary Osteosclerotic Anæmia.

In the majority of cases in which tumours metastasise in the skeleton,

any anæmia present is of a simple hypochromic type, but in rare instances there may be profound anæmia, of rather high colour index, with many nucleated red cells and myelocytes in circulation. This is perhaps most likely to happen when a carcinoma of the prostate gland disseminates miliary emboli throughout the skeleton, which give rise to a diffuse sclerosis of the bones, but it has also been found with secondary tumours in the bones from the breast or the stomach. Bence-Jones protein may be present in the urine.

EOSINOPHILIA

The function of the eosinophil cells is not known, though it is suggested that they protect the body against the absorption of foreign proteins or of abnormal products of protein metabolism. Their number is increased by certain drugs, such as emetine, and also by feeding with whole liver. There is a rare condition of *hereditary eosinophilia* which sometimes manifests itself in different members of a family, and in which the normal proportion of eosinophils and neutrophils is reversed; in such cases infection is attended by a neutrophil leucocytosis and a temporary diminution of the eosinophilia. A constitutional tendency of the same kind is probably present in a number of individuals, and explains the high eosinophilia that may sometimes appear from trivial or unusual causes. In the symptomatic eosinophilias tabulated below it is rare for the total white count to be much increased, or for the eosinophils to exceed 20 per cent., but occasionally they may constitute over 50 per cent. of a total white count of 50,000 to 100,000. The eosinophils are usually increased in:

1. Infestation by parasites, especially hydatid cysts, ankylostomiasis and trichiniasis.
2. Convalescence from acute diseases; they are diminished in the acute stage, except in cases of scarlatina in which there is a slight eosinophilia at the time of the eruption, and sometimes in acute rheumatism.
- 3.* Allergic states, such as asthma and hay fever.
4. In many skin diseases.
5. In Hodgkin's disease in about one-quarter of the cases, but rarely to a high degree; and in rare cases of malignant growths, more especially when the peritoneum is involved.
6. In myeloid leukæmia and erythræmia.

EOSINOPHILIA WITH SPLENOMEGALY.

Synonym.—Eosinophilic Leukæmia.

This is an uncommon syndrome in which enlargement of the spleen is associated with persistent eosinophilia; the liver and the lymph-glands may also be palpable. The total white count is usually between 10,000 and 25,000, but it may exceed 50,000 cells per c.mm.; eosinophils constitute from 20 to 80 per cent., the majority being mature and only a small fraction myelocytes. Anæmia, if present, is of moderate degree. Post mortem the hyperplastic bone-marrow is seen to be filled with eosinophils in all stages of development. Eosinophil cells are present in the other organs, especially the spleen and the lymph-glands, but here they are mainly adult cells. Areas of hæmorrhage

and fibrosis may be found in the spleen and the lungs, and granulomatous tumours have also been observed. The benign course of the disease in many instances, the absence of anæmia, and the small percentage of myelocytes in the blood and tissues are arguments against regarding the condition as a true eosinophilic leukæmia. It is probably not a disease entity, but a syndrome of varied ætiology. Some cases are examples of hereditary eosinophilia in its severer form; others are acquired on a basis of syphilis, malaria, hepatic cirrhosis, Hodgkin's disease and other known causes; and a few cases remain obscure. The prognosis is moderately good, but death may occur from intercurrent infection. Splenectomy is contra-indicated, as it aggravates the eosinophilia. Great improvement follows anti-syphilitic treatment in cases with a positive Wassermann reaction.

LYMPHOCYTOSIS

Little is known about the function of the lymphocytes, though they are believed to play an important part in the protection of the mucosæ and the defence of the body from chronic disease. They are increased by exposure to ultra-violet light, and diminished by excessive X-radiation and by vitamin deficiency. Lymphocytes are more numerous in the blood of children than of adults, constituting from 40 to 60 per cent. of a total count of 7000 to 9000 white cells per c.mm., and their reactions to disease are much greater in early life. There are few infections in childhood which may not now and again be associated with an extraordinarily high lymphocyte count. The lymphocytes are especially increased in whooping-cough, chicken-pox, small-pox, typhus, malaria, and most constantly in glandular fever (acute mononucleosis). In isolated instances of these various infections the lymphocytes may rise as high as 75 per cent. or more of a total count of 100,000 white cells per c.mm., and leukæmia may be suspected. Usually the absence of anæmia should quiet this suspicion. The lymphocytes are moderately increased in the stage of healing of acute infections, and in tuberculosis which is progressing favourably. They are diminished in miliary tuberculosis and lesions of the lymphoid tissues, such as glandular tuberculosis, Hodgkin's disease, carcinoma and lymphosarcoma.

MONOCYTOSIS

The monocytes have only been differentiated from the lymphocytes in recent years, and not much is known about their behaviour in disease. They are increased during and after the crisis in acute infections, and also in active tuberculosis and undulant fever. Very high counts are occasionally obtained in miliary tuberculosis, infective endocarditis, and putrid sore throat. Monocytosis is also present in the rare endothelial sarcoma or angiosarcoma of the spleen. This condition is probably related pathologically to the true monocytic leukæmias, which are uncommon and need special staining methods for their differentiation from other forms of acute leukæmia.

BASOPHILIA

The basophils are moderately increased in a number of diseases of the blood-forming organs, such as leukæmia, erythræmia and acholuric jaundice. The increase of basophil cells in myeloid leukæmia is sometimes of diagnostic importance, as it may be the only abnormality present during a remission.

LEUCOPENIA

The strict meaning of the word "leucopenia" is a diminution in the total white cell count, but as the granulocytes are chiefly diminished in leucopenia, the word is often used to mean a diminution in the granulocytes. In the interests of accuracy it is better to use the terms *granulocytopenia* or *neutropenia* to indicate a diminution in the number of granulocytes or neutrophils respectively. While the majority of infections induce a leucocytosis, it is characteristic of certain diseases that the white count is normal or diminished. The most important infections in which there is leucopenia are the enteric fevers, undulant fever, influenza and measles. As might be expected, leucopenia occurs in cachectic and debilitated states and in diseases of the blood-forming organs in which the leucopoietic tissues are depressed. There is a temporary fall in the number of leucocytes in the peripheral blood in anaphylactic shock and similar conditions, owing to collection of the cells in the internal organs.

When leucocytosis occurs in response to infection or other injury, the initial increase in the white cells is due to the mobilisation of the reserves which are present in the bone-marrow, but owing to the short life of the white cells, and their rapid depletion by emigration into inflammatory foci, the leucocytosis can be maintained at a high level only by a great acceleration in the formation of new white cells. If the bone-marrow fails to make good the loss of white cells a profound leucopenia develops, and serious and fatal results follow the unrestrained progress of the infection. It may also happen that the number of circulating white cells falls far below the level of health as a result of an unexplained decline in the regenerative power of the leucopoietic tissues, and then the bacteria which are constantly present in the surfaces of the body are enabled to invade the tissues, or the trivial infections to which all of us are exposed take on a malignant character. Failure of the genesis of white cells is strictly comparable and sometimes combined with aplastic anæmia, in which the erythropoietic tissues cease their function, and it may therefore be discussed under similar headings to those employed for that disease. Cases fall into the following groups :

(1) Leucopenia may be secondary to recognised disease of the blood-forming organs, such as pernicious anæmia and splenic anæmia. Leucopenia occurs almost invariably in aplastic anæmia, although it will be seen later that a failure in the genesis of the white cells may occur without anæmia. In the majority of cases of leukæmia, although the total white count is raised, the number of active neutrophil polymorphonuclear cells sooner or later falls below normal ; in rare cases there is an absolute leucopenia.

(2) Toxic substances such as benzol, arsenicals of the salvarsan group, and mustard gas, sometimes pick out the leucopoietic tissues for special

damage, the formative cells in the marrow being killed and the white cells of myeloid origin practically disappearing from the blood stream.

(3) Severe infections may have the same effect on the leucopoietic tissues ; there is much evidence that this is a rare event in individuals who were previously healthy, and that leucopenia in septic processes is more often due to the insufficiency of the marrow than to the virulence of the infection. Leucopenia resulting from septic infection differs from primary granulocytopenia in the invariable presence of septic foci, positive blood cultures, and at autopsy the septic type of splenitis.

(4) There is an important group of cases in which leucopenia develops as a result of aplasia or torpor of the leucopoietic tissues due to unknown causes. These cases are nowadays often called agranulocytosis, but the term "primary granulocytopenia" is preferable on etymological grounds.* We may then speak of the preceding groups of cases as secondary granulocytopenia, thus reminding ourselves that many of their clinical and pathological features are identical, and that the differential diagnosis of primary from secondary granulocytopenia may at times be difficult or impossible.

AGRANULOCYTOSIS.

Synonyms.—Malignant Neutropenia ; Primary Granulocytopenia ; Agranulocytic Angina.

Definition.—A disease characterised pathologically by profound leucopenia due to depressed function of the leucopoietic tissues, and clinically by an acute febrile illness, necrotic ulcerations and a high mortality.

Ætiology.—The essential feature of agranulocytosis is the blood picture and the consequent lowering of the powers of resistance. The total white blood count may be reduced to a few hundred cells. The reduction affects especially the granulocytes, which may be diminished to about 5 per cent. or completely absent. Examination of the bone-marrow sometimes reveals complete absence or at least a great deficiency of myeloid cells, while the other forms are present to a normal extent ; in other instances immature granulocytes are relatively abundant. There is much evidence that the leucopenia precedes the acute illness, and there are a number of instances in which a great diminution of the granulocytes has been found by chance during a routine examination, and weeks or months later the patient has succumbed to agranulocytic angina. Causes suggested for the leucopenia are—firstly, a constitutional weakness of the myeloid tissues comparable with premature baldness or precocious atheroma ; secondly, preceding infections or debilitating illnesses which have exhausted the bone-marrow ; and thirdly, a failure of the granulocytes to ripen normally to maturity. Usually the illness develops without warning or prodromata. It occurs most frequently and most typically in middle-aged women, but it may affect either sex or any age, and is by no means uncommon in childhood.

Pathology.—Necrotic, ulcerative or gangrenous lesions are present, most constantly in the mouth and pharynx, but they may affect any part of the alimentary canal, the rectum, and in women the vagina. This localisation is probably explained by the abundant presence of more or less virulent bacteria on these mucosæ and their liability to small traumata. Many organisms have been isolated from the foci, Vincent's organisms being most

frequently encountered. A similar multiplicity of organisms has been demonstrated in the blood stream, but it is probable that all these organisms are secondary invaders. The lungs are often consolidated at their bases. Oedematous or brawny swellings may be present about the teeth, the neck, in the subcutaneous tissues or elsewhere. The inflammatory infiltrates are almost entirely made up of lymphocytes, while there is an almost complete absence of granulocytes.

Symptoms.—The disease was known to physicians of the last century under the descriptive title of putrid sore throat, and some of the cases described as Ludwig's angina, cancrum oris and noma are also manifestations of it. The onset is acute, sometimes with rigors, and the patient complains of aching pains in the limbs and sore throat, and is rapidly prostrated. The temperature is high, ranging from 100° to 105° F. In the majority of cases ulcero-membranous lesions soon appear on the tonsils and gums, and the cervical glands may be enlarged, with surrounding brawny induration. The gangrenous process may spread along the œsophagus, and necrotic lesions may develop in the duodenum, the small and large intestine, the rectum, the vulva or the skin. In some cases these areas are affected without any involvement of the mouth or pharynx, and in rare cases the sole infective lesion present may be a mild redness of the throat without any other tissue or blood infection. The patient is pale, but not anæmic. The liver and the spleen may be palpable, and jaundice is an occasional complication. As the disease advances, the usual symptoms of a profound toxæmia appear.

Diagnosis.—The diagnosis depends chiefly on the blood picture. The disease can usually be differentiated from the secondary granulocytopenias by a careful history and examination. Most confusion will arise with acute leukæmia in its leucopenic phase, but the different age and sex incidence of agranulocytosis, the absence of any hæmorrhagic tendency, and the absence of immature white cells will usually settle the diagnosis.

Course and Prognosis.—Spontaneous recovery may occur, but the mortality of untreated cases is about 75 per cent. In the fulminating type the patient succumbs in two or three days. In the usual acute type, death or recovery occurs within a few weeks. Subacute or chronic forms of the disease are occasionally seen in which the illness is protracted through several months. Relapses are not uncommon, occurring after an interval of months or more than a year of good health. There may be more than one relapse, suggesting a strong constitutional tendency to the disease.

Treatment.—Transfusion is not advisable unless the patient is anæmic, as it may be followed by a further fall in the white count. If a transfusion is necessary, it is suggested that the donor should first receive an injection of a leucocytic stimulant, such as one of the nuclein derivatives, and that the blood should be taken at the height of the leucocytosis, so that as many white cells as possible may be transfused. Much more success has been obtained by the injection of leucocytic stimulants into the patient. A large number of patients have now been treated by Jackson and co-workers with a nuclein derivative known as Nucleotide K-96, and the mortality has been reduced to 25 per cent. Ten c.cm. are injected intramuscularly twice a day until the white count has definitely risen above its initial level. Ten c.cm. are then given intramuscularly once a day until the white count has been normal for several days. Little or no favourable result is to be expected

before the third day, and usually not before the fifth day after treatment has begun. The same treatment is indicated in cases of sepsis with a low white count. The only other specific treatment which has seemed to influence the disease is the application of small, stimulating doses of X-Rays to the bones. For local treatment the mouth may be sprayed with a saturated solution of potassium chlorate, and ulcerated areas then swabbed with a solution of copper sulphate, 10 grains to an ounce of water. Surgical intervention is unwise until the illness has taken a decided turn for the better, or frank suppuration has occurred. General treatment suitable to an acute febrile illness should not be neglected, but over-treatment should be avoided.

LEUKÆMIA

Synonym.—Leukosis.

Definition.—Leukæmia is a morbid condition characterised by widespread hyperplasia of the leucopoietic tissues, either myeloid or lymphatic, which is usually associated with qualitative and quantitative changes in the white cells of the circulating blood.

Ætiology.—The ætiology is unknown, and the disease appears to occupy an intermediate position between the reaction to infections and noxious agencies on the one hand and the true neoplasms on the other. Leukæmia occurs in the lower animals also, and (like the sarcomata of these animals) it is sometimes transmissible by cell-free filtrates. In its more acute forms in man it often resembles an infection, and very similar changes in the blood and the blood-forming organs may sometimes be produced by infections and similar clearly apprehended agencies; it is difficult, however, to reconcile the tumour-like growths which sometimes develop in leukæmia with a hypothesis of infection. It differs from the ordinary neoplasms in being a system-disease, and affecting the whole organ simultaneously. The neoplastic hypothesis presents fewer difficulties, the diffuse character of the lesion being explained by the labile character of the leucopoietic tissues and being paralleled by the diffuse carcinoma of cirrhotic livers. There is much similarity between leukæmia and erythræmia, and at times the two diseases appear to occur simultaneously, an erythro-leukæmia. Heredity is not known to play any part in the incidence of leukæmia. In a few instances the disease has followed injuries to the bones.

Classification.—We might expect to find forms of leukæmia corresponding to each of the different types of white blood cell, and classify them accordingly. In practice it is found that the only forms of leukæmia which occur at all frequently are those which involve predominantly the neutrophils and their precursors, or myeloid leukæmia, and those which involve the lymphocytes, or lymphatic leukæmia. Eosinophilic leukæmia has already been discussed, and a basophil leukæmia is not known to occur. True monocytic leukæmia has been observed, though many cases so described are actually myeloblastic leukæmia; monocytic leukæmia has an acute course, causing rapid anæmia with many nucleated red cells, and though of great interest to the morphologist, for practical purposes it is best included in acute leukæmia. In leukæmia the immaturity of the cells is equally as important as the type of cell present, and for clinical work the leukæmias are therefore described as chronic myeloid leukæmia, chronic lymphatic

leukæmia, and acute leukæmia: Whichever strain of cells is affected, the disease breeds true, and the two groups of cells are never involved simultaneously. Confusion has sometimes arisen owing to the ease with which very immature cells of the myeloid series, the myeloblasts, can be mistaken for lymphocytes. In acute leukæmia the cells may be so very immature that it is impossible to determine their origin, but the clinical features of acute lymphatic and acute myeloid leukæmia are identical.

1. CHRONIC MYELOID LEUKÆMIA.

Synonyms.—Myelocytic Leukæmia; Spleno-Medullary Leukæmia; Chronic Leukæmic Myelosis.

Ætiology.—The disease is more common in males, who make up 60 per cent. of the cases. It is very rare before puberty, and more than half the cases begin between 30 and 50, the greatest incidence being between 35 and 45.

Pathology.—The changes which are found in the body are almost confined to the hæmopoietic organs. The bone-marrow is firm and fleshy, pale pink or grey in colour, rarely of a greenish hue. The predominant cell is the myelocyte, but there are also large numbers of myeloblasts and nucleated red cells. The spleen is usually enormously enlarged, but its outline is preserved; its surface is smooth, its consistence firm, its colour on section a greyish-red, usually mottled with infarcts. Microscopically the Malpighian corpuscles are obliterated, and the pulp is filled with myeloid cells and resembles the bone-marrow. The liver is large, firm, and of a pale yellow tint, and its capillaries contain large numbers of myelocytes. The other organs may show anæmia, hæmorrhages, and infiltration with myelocytes.

Symptoms.—Early symptoms are easy fatigue, slight loss of weight and strength, and gastro-intestinal disturbances, but the patient may first complain of the enlargement of the abdomen due to the increasing size of the spleen. The anæmia at this time is not marked, indeed the appearance is not seldom one of good health. Pain in the left side is sometimes felt, either as a result of the dragging weight of the enlarged spleen or from perisplenitis over an infarct. The average duration of symptoms before medical advice is sought is about a year. Fever is commonly slight, and there are often long periods of normal temperature interrupted now and then by small rises of short duration to 101° F. or 103° F. The basal metabolic rate is increased. Tenderness is often present over the sternum, more marked during exacerbations of the disease.

On examination the striking feature is the size of the spleen. It occupies the greater part of the left side of the abdomen, often reaching to the iliac crest below the middle line at the umbilicus. It forms a hard smooth tumour, with rounded edges, not tender to palpation and easily recognised by the characteristic notches in the anterior margin. The size tends to vary in the course of the disease, often leading to false hopes as to the efficacy of treatment. Sudden enlargement is due to hæmorrhage or infarction, and marked diminution nearly always occurs with the approach of death. The liver is larger than normal, and smooth. The lymph-glands are rarely palpable, except sometimes near the end. Impairment of vision may occur from leucocytic accumulations or hæmorrhages in the retina, while involvement of the inner ear may lead to deafness and Ménière's syndrome.

In the later stages the anæmia becomes severe and cachexia develops. Ascites and œdema make their appearance, the heart weakens, and the patient becomes emaciated. Hæmorrhage is frequent, but rarely lethal. Death occurs from exhaustion or from intercurrent infection. It should be noted that infection may produce a temporary improvement in the blood picture, but such a remission is often followed by an aggravation of the disease, which then pursues an acute and rapidly fatal course. Conversion of chronic into acute leukæmia may also happen spontaneously.

The Blood.—The principal characteristics are progressive loss of hæmoglobin and of red cells, and increase, frequently enormous, of the leucocytes. The white count ranges from 100,000 to 1,000,000 cells per c.mm., values about 400,000 being most usual. The increase is mainly composed of cells of the granulocyte series. The typical cell is the neutrophil myelocyte, which constitutes 20 to 40 per cent. of the total; but the neutrophil, eosinophil and basophil polymorphonuclears are also increased, eosinophil and basophil myelocytes are present, and occasional myeloblasts are encountered. The anæmia is of the hypochromic type, and as it becomes more severe, anisocytosis and polychromasia develop, and nucleated red cells appear in the blood. The platelets are normal or slightly increased at the beginning of the disease, but decrease in the terminal phase.

Diagnosis.—This is usually made with ease from the characteristic blood picture and the great splenic enlargement, though difficulty may arise when the white cells fall to normal or subnormal values as a result of excessive treatment or of a natural remission of the disease. In these circumstances the presence of immature white cells and of basophilia may indicate the correct diagnosis.

Course and Prognosis.—Chronic myeloid leukæmia is invariably fatal. The average duration of life is just over 3 years from the onset of the disease, or 2 years after coming under treatment. There is no evidence that treatment prolongs life, though it greatly increases the comfort of the patient. In any large series exceptional cases are observed in which life is prolonged for 10 to 20 years. One of my cases was under observation for 22 years, from age 38 to her death from bilateral hydronephrosis at the age of 60; in her the disease seemed to be of a benign character, and though there was great splenic enlargement, the highest white count was only 35,000, with 26 per cent. myelocytes. At the other extreme are subacute cases which shade indefinitely into acute leukæmia. The prognosis in an individual case will depend on the general condition of the patient and the presence or absence of cachexia, the degree of anæmia, and the height of the white count, very high and also very low values being unfavourable. Enlargement of lymph nodes and the appearance in the blood of large numbers of myeloblasts are each unfavourable signs. (See also under Treatment.)

Treatment.—The treatment of chronic myeloid leukæmia is practically confined to the use of X-Rays and arsenic. Both agents owe their reputation to their remarkable power of producing a temporary remission in the disease. The natural course of chronic myeloid leukæmia is steadily downhill, and during the latter half of the untreated disease the patient is confined to his bed, cachectic and miserable. After a course of treatment with X-Rays or arsenic, the patient is restored to what he feels his normal condition. The spleen usually remains enlarged and the blood abnormal, but in rare cases

the blood returns almost to normal and the spleen recedes beneath the costal margin. Such a remission lasts from a few months to a year, when repetition of the treatment again produces improvement, though not so complete as before. After a varied number of cycles treatment finally becomes ineffective, and a time arrives when despite all efforts the patient becomes steadily worse. The period of decline is usually swift, and in the majority of cases death occurs within four or five months of entering this final phase. Splenectomy is contra-indicated in leukæmia, and leucotoxic drugs such as benzol and thorium-X are not without danger. Anti-leucocytic sera have been employed, but have not emerged from an experimental stage.

2. CHRONIC LYMPHATIC LEUKÆMIA.

Synonym.—Chronic Lymphadenosis.

Definition.—A chronic overgrowth of the lymphatic tissue throughout the body, accompanied by an increased number of lymphocytes in the blood.

Ætiology.—The disease is one of middle and later life, and is never met in children. The average age of incidence is 55, over ten years later than chronic myeloid leukæmia. Males are affected about four times as often as females. The cause is not known. Chronic lymphatic leukæmia is much the rarest of the three main types of leukæmia, and it accounts for less than one-sixth of all the cases.

Pathology.—Post mortem the striking feature is the enlargement of the lymph-glands and other lymphoid tissues. The glands are seldom larger than a walnut, discrete, homogeneous, and pinkish-grey on section. The lymphoid tissue of the pharynx is hypertrophied, and lymphoid nodules may be present in the intestines, the kidneys and elsewhere. The liver and spleen are uniformly enlarged, the bone-marrow is hyperplastic, and grey or greyish-red in colour.

Symptoms.—The disease may be present for months or years before the patient feels it necessary to consult a physician. Swelling of the glands is usually the first symptom to attract attention, or the patient may complain of increasing tiredness and loss of weight. Less frequently enlargement of the tonsils is first noticed, or enlarged glands and spleen are discovered by chance during a routine examination. In exceptional cases a tumour extirpated by the surgeon is found to be a lymphoma, and subsequent examination of the blood reveals chronic lymphatic leukæmia. Other early symptoms are itching eruptions of the skin, and impotence.

In typical cases all the superficial lymph-glands are enlarged. The enlargement is moderate and the glands are rarely so big as in Hodgkin's disease or lympho-sarcoma. They are freely movable and not adherent to one another, moderately hard, and do not alter in consistence during the course of the disease. Spontaneous fluctuations in their size may occur. In atypical cases only one group of glands may be enlarged. The tonsils may be hypertrophied, the spleen is nearly always palpable, though it does not often extend more than a hand's breadth below the costal margin, and the liver is enlarged. Tenderness of the sternum or of the long bones is unusual. Hyperplasia of the lymphoid tissue in various parts of the body may lead to the formation of tumours or other unusual symptoms. Nodular lesions, infiltrations and actual tumours may develop in the skin. Enlargement of

the thymus and the mediastinal lymph-glands may produce the signs of an intrathoracic tumour. Lymphomata may develop in the breast or other organs. The salivary and lachrymal glands may be symmetrically enlarged, producing one of the varieties of Mikulicz's syndrome.

The Blood.—The red cells and hæmoglobin are unaffected in the early stages, but, later, severe anæmia develops, with anisocytosis, polychromasia and nucleated red cells. The platelets are unaffected till the end, and hæmorrhage is rare. The total white count is increased, usually to about 200,000 cells per c.mm., but not to the high level seen in chronic myeloid leukæmia. Lymphocytes predominate and may constitute 95 to 99 per cent. of the white cells. The majority are small lymphocytes, though a few large lymphocytes are nearly always present. The nuclei may be more deeply indented than normal, and azur-granules are usually absent. The absolute number of polymorphs is unaltered, and no myelocytes are present. It is probable that the proliferation of lymphoid tissue in the glands and elsewhere may precede by some time the increase of lymphocytes in the blood stream. In rare cases the blood is normal when the patient first comes under observation, but, later, the characteristic picture develops (*aleukæmic leukæmia*); or the total white count may not be increased, though there is a high percentage of lymphocytes.

Diagnosis.—Only in the rare aleukæmic cases is diagnosis difficult. Points of importance are the generalised enlargement of the lymph-glands, their uniform consistence and moderate size, and the enlargement of the liver and spleen. Biopsy of a gland may assist.

Prognosis.—The disease is invariably fatal. The average duration is $3\frac{1}{2}$ years from the onset, or about 18 months after coming under treatment. A few cases are more chronic, and exceptionally life may be prolonged for 10, 15 or 20 years. Death occurs from cachexia, hæmorrhage, or most commonly from intercurrent infection, sepsis being a very dangerous complication. It is doubtful whether treatment greatly modifies the course of the disease.

Treatment.—X-Rays should be applied to the lymph-glands, but not to the spleen, as irradiation of the spleen produces little benefit and is often followed by severe reactions. Arsenic and ultra-violet radiation may also be employed. Symptomatic relief has followed the use of Lugol's iodine solution in doses of about 10 minims thrice daily.

3. ACUTE LEUKÆMIA.

Ætiology.—Acute leukæmia is not a very rare disease, but many cases go unrecognised, because of the close simulation of other diseases and the difficulty of diagnosis without careful examination of the blood. It is more frequent in childhood and early adult life, but may affect any age. Males predominate in a ratio of about 2 to 1.

Symptoms.—The onset is usually abrupt, and more than half the cases begin with symptoms regarded as a cold, influenza or bronchitis; it is only when the infection fails to respond to treatment and the patient remains prostrated that a more serious disease is suspected. Other early symptoms are ulcerative stomatitis, or tonsillar enlargement with sore throat, and some cases first come under the physician's care after a prolonged hæmorrhage.

from tonsillectomy, dental extraction or some trifling operation, which has left the patient exsanguinated. The course of the disease varies from fulminating cases in which the patient succumbs within a week, through cases of average acuteness with a duration of less than 2 months, to subacute cases which shade indefinitely into chronic leukæmia. Usually the rapid development of anæmia, weakness and loss of weight soon compels the patient to take to his bed. He complains of sore throat, headache and pain in the bones. The temperature becomes high and purpuric manifestations set in, which aggravate the anæmia or bring the patient's sufferings to an abrupt termination by loss of blood or cerebral hæmorrhage.

On examination the extreme pallor and the enlargement of the superficial lymph-glands, especially those in the neck, first attract attention. The pallor is most striking when there are in addition purpuric hæmorrhages into the skin, varying in extent from a pinpoint to large patches which may break down and ulcerate. The size of the spleen varies; usually it is easily palpable, but it may not be felt, or it may be greatly enlarged. The liver may be enlarged. The lungs may show bronchitis, broncho-pneumonia, or pleurisy, with or without effusion. Pericarditis and endocarditis may occur. The mind usually remains clear to the end. Certain symptoms may be so prominent as to colour the whole clinical picture and give a special aspect to the disease. In the anginal type, there is necrotic ulceration of the tonsils or other areas of the buccopharyngeal mucous membrane, or bleeding from the gums, complicated by secondary infection. In the hæmorrhagic type, purpura and hæmorrhages are the predominant features, and the disease may be mistaken for purpura hæmorrhagica. There may be hæmorrhage from any of the mucosæ, and in one of my cases there was so much blood in the urine that firm clots formed in both pelves and ureters, leading to death from suppression of urine. Disturbances of vision or deafness may result from hæmorrhage into the retina or the labyrinth. The fever and slight splenomegaly may be suggestive of some systemic infection, and there may be leucopenia and an eruption resembling the rose spots of typhoid fever.

In the more subacute forms of the disease, tumours may develop in various parts of the body. These are composed of undifferentiated white cells and infiltrate the surrounding tissues like a malignant growth. Plum-coloured nodules appear in the skin or in the gastro-intestinal tract, in the latter situation leading to vomiting or profuse diarrhœa, often blood-stained in character, or to intussusception of the bowel. In the abdomen or in the mediastinum large growths may develop from the lymph nodes or the thymus, compressing and infiltrating the adjacent structures. Tumours of the bones have been distinguished by the special title of *chloroma*, owing to the greenish colour sometimes seen in the freshly cut surface of the growth. They have a predilection for the subperiosteum of the orbit, and cause headache, deformity of the temporal and frontal bones, exophthalmos, proptosis, papillœdema and swelling of the veins of the head, neck and face. They may, however, occur in other parts of the skeleton, and sometimes seem to arise within the bone, which is expanded over them in a brittle shell. The spinal meninges may be invaded, with consequent transverse myelitis, while infiltration of the nerve roots leads to peripheral nerve palsies. It is a curious feature of these neoplastic phenomena that they often begin with a very atypical blood picture, the total white count not

being greatly increased and in rare cases the differential count being normal at the onset, though the typical blood picture of leukæmia appears later.

Hæmatology and Pathology.—The outstanding feature of the blood in acute leukæmia is the presence of a large number of mononuclear cells of a primitive type, except in rare cases of acute lymphatic leukæmia in which the predominant cells may be typical lymphocytes. In something like 90 per cent. of all cases of acute leukæmia these primitive cells belong to the myeloid series, the majority being myeloblasts. They are usually larger than the normal white cells; their nucleus, which is round or oval, consists of a pale-staining chromatin reticulum in which 4 or 5 nucleoli may be distinguished; the deep blue cytoplasm contains no granules. Careful staining often reveals some cells with a few myelocyte granules, and a larger or smaller number of typical myelocytes may be present, especially in the more chronic cases. The total white count is rarely high in the early stages of the disease, usually not exceeding 25,000 to 30,000 per c.mm., but as a rule there is a rapid rise to 100,000 or more before the termination. Primitive cells constitute 90 per cent. or more of the white blood cells. Sometimes the total number of white cells is diminished and the count may be below 1000, the majority of the cells being myeloblasts. Such *leucopenic* cases are very prone to necrotic ulcerations and infectious complications. Much more rarely both the total and the differential white count are normal at the onset of the disease, as if the morbid process had not yet invaded the blood stream—*aleukæmic leukæmia*.

At the onset of the disease the hæmoglobin and red cells may be normal, but the overgrowth of the premature white cells in the marrow and the hæmorrhages soon lead to a profound anæmia, usually of an aplastic or hypochromic type. In a few instances there is a surprising response on the part of the red cells, which may simulate pernicious anæmia. Numerous normoblasts and megaloblasts appear in the blood stream, there may be frank megalocytosis, van den Bergh's reaction is positive, and at post-mortem excess of iron pigment may be found in the liver and spleen. The number of platelets is diminished in almost all cases, and sooner or later this is reflected in the hæmorrhagic character of the disease. The bleeding-time is prolonged, the tourniquet test is positive, and the clot may not retract well.

The post-mortem findings vary only slightly from those of chronic leukæmia. There is diffuse hyperplasia of the leucopoietic tissues in the marrow, lymph-glands and spleen, and all the tissues are infiltrated with myeloblasts, which may form nodules or tumour-like masses in various situations. Terminal hæmorrhagic and infectious lesions are rarely absent.

Diagnosis.—Acute leukæmia may simulate a number of diseases, among which may be mentioned the severe systemic infections, septic or diphtheric inflammation of the mouth and throat, scurvy and the hæmorrhagic diseases, malignant disease or tumours of bone. Usually the blood picture will be decisive, but the possibility of agranulocytosis or of septic infection should be remembered in cases in which only a few immature white cells are present in the blood. Glandular fever may cause confusion in the early stages, but the benign course and the absence of anæmia and hæmorrhages will soon differentiate it from leukæmia. The blood picture in acute leukæmia

is sometimes suggestive of pernicious anæmia, but the other symptoms of that disease and its favourable response to liver are absent.

Prognosis and Treatment.—Acute leukæmia is almost invariably fatal, but I have already mentioned the occasional occurrence of cases indistinguishable from acute leukæmia except by their recovery, and there are few physicians of experience who, at some time or other, have not had to retract the diagnosis of acute leukæmia. Onset at an early age, high fever and great immaturity of white cells all point to a speedy fatal issue. Death often comes by intercurrent infection, especially in the leucopenic cases, or as a result of hæmorrhage. Rarely the disease may pass into a subacute or chronic form, and death be postponed for a year or longer. Treatment is mainly directed to checking infection, especially about the mouth and throat, and preventing hæmorrhage. Intravenous injections of salvarsan may cause the necrotic ulcerations to heal. The only remedy which appears to modify the course of the disease is repeated blood transfusion. This operation should be carried out with the most scrupulous care, as the reactions are alarming, but the risk is often justified by the result. It may bring the patient into a suitable condition for X-Ray treatment, which is otherwise contra-indicated by the low number of normal polymorphonuclear cells.

4. MULTIPLE MYELOMA.

Synonym.—Kahler's Disease.

Definition.—A disease characterised by the development of multiple tumours in the skeleton, which arise from cells of the bone-marrow.

Ætiology.—The disease is closely related to leukæmia, but differs from it in the sharper localisation of the neoplasia, the absence of enlargement of spleen or lymph-glands, the much smaller tendency for the abnormal cells to enter the blood stream, and the frequent appearance of Bence-Jones protein in the urine. Intermediate forms occur with features of both diseases. The ætiology is unknown. It is a disease of middle and later life, occurring most frequently in the fifth, sixth and seventh decades, and affecting males twice as often as females.

Pathology.—Multiple, grey or reddish-grey, sharply defined tumours are present in the bones, thinning the cortex and leading to deformities and fractures. Rarely a diffuse hyperplasia of the marrow is associated with foci of tumour formation. The skull, vertebræ, ribs and pelvis are most commonly attacked. Tumours may also be found outside the skeleton in the tonsils, liver, spleen, kidneys or sex-glands, and these tumours may even precede those in the bones. The cells, which are of one type in any given case, may be myeloid (myeloid myeloma), or lymphatic in origin (plasma-cell myeloma); erythroblastomata are also described. It is, therefore, a growth of marrow cells and should not be confused with tumours of the bones themselves, such as the giant-cell tumour or osteoclastoma.

Symptoms.—The disease develops insidiously, with neuralgic pains in the bones and back. Cachexia is of early onset, and compression myelitis or neuritis may occur. The diagnosis may be very difficult until attention is directed to the bones by spontaneous fractures, or the appearance of painful swellings, varying in size from a walnut to a man's fist. The discovery of

Bence-Jones protein in the urine is an important sign, but it is only present in about half the cases. It is an abnormal albuminous substance, which is precipitated on heating the urine to 50° C., but dissolves on boiling; it reappears when the urine cools, and solution and precipitation may be repeated indefinitely by alternately boiling the urine and letting it cool. Bence-Jones protein is not confined to multiple myeloma, being found in other tumours of bone, and more seldom in other conditions, such as myeloid leukaemia. The diagnosis is confirmed by X-Ray examination, when the tumour appears as holes cleanly punched out in the bones. The blood shows no special changes, merely a hypochromic anaemia, which becomes aggravated in the terminal stages. The leucocytes are at the upper limit of normal, and a few myelocytes and nucleated red cells may appear. In a few instances cells of the type which constitutes the tumour enter the blood stream in larger or smaller numbers.

Diagnosis, Prognosis and Treatment.—The condition must be differentiated from syphilis, tuberculosis, and secondary tumours of bone. The X-Ray appearances and the Wassermann reaction are usually decisive, but if necessary biopsy may be performed. The prognosis is hopeless, death usually occurring in 2 years, though rarely it may be postponed for 5 to 10 years. X-Ray treatment may alleviate the pain but it does not retard the progress of the disease.

THE HÆMORRHAGIC DISEASES

The hæmorrhagic diseases are the most unsatisfactory section of the diseases of the blood. Our knowledge of the physiological processes whereby bleeding is arrested in the healthy person is incomplete, and there is no agreement about so fundamental a factor as the reason blood clots when it is shed. Still less is known about the morbid conditions which give rise to pathological hæmorrhage. In clinical work there has been a tendency to emphasise individual signs and to use them as a means of classification of the hæmorrhagic diseases, quite regardless of the diverse clinical conditions in which they are manifested. These signs may be due to entirely different causes in different diseases, and the course of the disease and the outlook for the patient vary accordingly. It is most important to regard the patient as a whole, without undue preoccupation with isolated symptoms. In this way we can recognise a group of hæmorrhagic states which are obviously the result of well-recognised primary diseases, and whose prognosis and treatment are dependent on the primary disease. We can also recognise other hæmorrhagic states in which certain symptoms and a certain course are so constantly repeated as to make them clinical entities, so that experience enables us to determine their prognosis and treatment. The blood picture is, of course, a most important element in the diagnosis, and it is convenient to approach the problem of the hæmorrhagic diseases by considering the parts played by the plasma, the blood platelets, and the vessel wall in the arrest of hæmorrhage.

The plasma.—When there is delay in the coagulation of the plasma, the fault is manifested clinically by excessive bleeding from wounds. Bleeding does not usually occur spontaneously, the duration of bleeding from skin

punctures is not excessively long, the capillaries are not unduly fragile, and the morphology of the platelets is normal. Hæmophilia is, of course, the typical example of this condition, while it also occurs in *melæna neonatorum*. In excessively rare cases hæmorrhagic states associated with delayed coagulation of the blood are due to a shortage of calcium (hæmophilia calcipriva), or of fibrin (fibrinopenia). States resembling hæmophilia may also occur in diseases of the liver (pseudo-hæmophilia hepatica), and very rarely in syphilis (pseudo-hæmophilia syphilitica); it is not known whether they are due to shortage of fibrin, or to excess of the substances which normally inhibit clotting in the blood stream, or to both causes. As the cardinal feature of hæmophilia is delayed coagulation of the blood, terms such as "pseudo-hæmophilia," or "hæmophilia-like" should be restricted to conditions of which this is the characteristic feature, and should not be applied to hæmorrhagic states in general.

The blood platelets.—The platelets are the third formed element in the circulating blood. They are spherical or oval, non-nucleated disks, with an average diameter of 2 to 3 microns, and with a hyaline cytoplasm which contains numerous granules. The average number of platelets is from 250,000 to 450,000 per c.mm., but there are great variations in health, and according to the method of estimation employed. The platelets are believed to be produced by the megakaryocytes in the bone-marrow, and after a brief life of a few days they are phagocyted by the cells of the reticulo-endothelial system. Large numbers of platelets are present in the spleen, but it is not certain whether they are held there in reserve, or in process of destruction. The platelets play an important part in the arrest of hæmorrhage, sealing wounds in the endothelial lining of the vessels, promoting the coagulation of the blood, and securing the firm adhesion of the clot. When the blood platelets fall below 40,000 per c.mm., a group of symptoms usually appears which is known as purpura hæmorrhagica, though the term *hæmogenia* is preferable, inasmuch as purpura is not a constant symptom. In the purpura of thrombocytopenia, the cutaneous hæmorrhages are usually small round spots, not elevated above the surface, and they change their colour, which does not pale on pressure, from the bright red of their first appearance to purple or brown as they fade. Frequently, successive eruptions present all shades of colour from bright red to dingy brown in the same patient. Absence of elevation above the surface is the rule. The smaller spots are called "petechiæ," the lines and streaks "vibices," and the larger irregular patches "ecchymoses." These larger patches in rare instances become gangrenous and slough; such gangrene happens in the type known as purpura fulminans. Hæmorrhages occur spontaneously in the skin, from any of the mucosæ, and more rarely internally, although the coagulation time of the blood is normal. Certain associated phenomena are usually present in cases of thrombocytopenia.

1. The platelets are very variable in size and shape, and giant platelets may be present.

2. The blood clots in the normal time, but the clot does not retract and express the serum as rapidly and completely as in health.

3. The bleeding time is greatly increased. If the blood from a sharp prick in the finger is soaked off with a filter paper without pressure every 30 seconds, bleeding normally ceases in one to two and a half minutes, but

if the platelets are defective it may be prolonged even to an hour or more.

4. The capillaries are more fragile than normal. The sphygmomanometer is applied to the upper arm and the pressure is raised just sufficiently to obliterate the pulse at the wrist for two minutes. When the platelets are defective, a coarse purpuric rash may appear on the lower arm.

The endothelium.—A hæmorrhagic tendency due to a pure endothelial lesion is characteristic of scurvy, in which the plasma and the platelets are normal, but the fragility of the capillaries is much increased. The same is true of the purpura of old age and nervous purpuras, such as stigmatisation. The hæmorrhagic states present in uræmia and other cachectic conditions are probably due to endothelial damage. When hæmorrhagic states are due to lesions of the capillaries, plasma may also pass through the endothelial lining, producing wheals, local œdema of the tissues and urticaria, and the purpuric areas may be elevated above the surrounding skin.

One of the great difficulties of the hæmorrhagic diseases is that the phenomena which may be associated with thrombocytopenia are inconstant, and that there is often great disparity between the platelet level and the hæmorrhagic tendency. In experimental animals extreme thrombocytopenia may be unassociated with symptoms, and the tourniquet test suggests that there is also an endothelial lesion in hæmorrhage due to shortage of platelets. It is remarkable that the fasting blood clots normally in thrombocytopenic states; normal blood will not clot when the platelets are removed, unless it has been taken at the height of digestion. Even though the tests of the coagulation time and the bleeding time give normal results, it cannot be assumed that a patient will not bleed excessively if exposed to injury. The previous history of the patient and the clinical experience of similar cases should be given more weight than the laboratory tests.

1. SYMPTOMATIC HÆMORRHAGIC STATES

A hæmorrhagic tendency may develop in a heterogeneous collection of diseases, and it is difficult to present the subject at all formally. The most important group is constituted by the *infectious diseases*. Purpura and a hæmorrhagic tendency have been observed in infections with the pyogenic cocci, scarlatina, chicken-pox, small-pox, diphtheria, the enteric fevers, typhus, malaria, and gonococcal and meningococcal septicæmia. They have also been observed in chronic septic infections, such as focal sepsis and malignant endocarditis, and in tuberculosis, especially the miliary form. In all such conditions we have reason to believe that the endothelial lining of the vessels is damaged. The platelet count varies from case to case. It may be increased, and then thrombosis may develop in the midst of hæmorrhagic manifestations; it may be normal; or it may be diminished, when the hæmorrhagic tendency may be very severe, such cases being known as purpura fulminans. In typical cases the platelets are diminished during the acute period of the illness, but increase in convalescence and afterwards fall to normal limits.

The cause of the thrombocytopenia of infections is not known. It has been suggested that there is an increased utilisation of platelets in such illnesses, either to combat the infection or to repair the lesions of the vessel

walls. In some cases it is undoubtedly due to depression of the function of the bone-marrow in producing platelets, and this should be suspected more especially when there is leucopenia also. We shall see later that the spleen plays an important part in one group of hæmorrhagic states associated with thrombocytopenia, but I do not think there is any evidence to inculcate the spleen in the hæmorrhagic states which complicate infectious illnesses. It may be taken as axiomatic that splenectomy should never be performed either in acute or in symptomatic purpura hæmorrhagica. Treatment should be directed to the primary malady, and the hæmorrhages should be controlled by local measures, supported if necessary by transfusions.

A second group of symptomatic hæmorrhagic states is constituted by *chronic nutritional disturbances and cachexias*, of which chronic nephritis is an example. Here also we may mention the purpura which occasionally occurs in pregnancy. Malignant disease of the stomach is occasionally complicated by purpura hæmorrhagica; in the only two cases I have seen there was extreme thrombocytopenia.

A third group is produced by *organic and inorganic poisons*, such as salvarsan and sanocrysin. Here there may be both endothelial damage and thrombocytopenia.

A fourth group is associated with chronic *splenomegaly*, such as occurs in splenic anæmia and Gaucher's disease. Here there is thrombocytopenia, which is usually relieved by splenectomy.

A fifth group is the result of *diseases of the blood-forming organs*. The proliferation in the bone-marrow of the megaloblasts in pernicious anæmia, or of the immature white cells in leukæmia, may cause a pressure atrophy of the megakaryocytes and consequent thrombocytopenia. The same effect may be due to other tumour-like lesions of the bone-marrow.

Aplastic anæmia requires special mention. In discussing this disease I have already described cases in which the red cells are predominantly affected (aplastic anæmia), and others in which the white cells are predominantly affected (agranulocytosis). Cases also occur in which the platelets are chiefly affected, and they are known as *malignant thrombocytopenia*, or aleukia hæmorrhagica. The term "aleukia hæmorrhagica" is unnecessary, but it stresses the leucopenia, which is nearly always present in these cases. The disease should be recognised by its acute and rapidly fatal course and by the absence of any signs of regeneration in the white cells or the red cells. The spleen is not enlarged, and splenectomy is useless. Treatment should be directed to keeping the patient alive by transfusions in the hope that the bone-marrow may recover its functions.

We can now discuss the hæmorrhagic states which seem to be disease entities, and I will describe first those which are due to faults in the plasma—hæmophilia and melæna neonatorum; secondly, those which are due to faults in the platelets—the hereditary hæmorrhagic diathesis, or constitutional hæmogenia, and essential thrombocytopenia or hæmogenia; and thirdly, those which are due to faults in the vessel walls—Henoch's purpura and hereditary telangiectasia. It is noteworthy that three of these six conditions are hereditary diseases.

2. HÆMOPHILIA

Definition.—A rare hereditary disease of males, characterised by a tendency to uncontrollable hæmorrhage and a great prolongation of the coagulation time.

Ætiology.—The disease is inherited by the law of Nasse, according to which it is transmitted only by females and manifested only by males. In Mendelian terminology it is a sex-linked recessive, and theoretically it might be expected to occur in females in the proportion of 1 to 200 affected males. In practice hæmophilia in the female has never been authenticated, nor does it ever occur in an acquired form.

Pathology.—All that can be said is that hæmophilic blood does not clot under ordinary conditions, though it clots spontaneously at a temperature of 30° to 40° C. The protein complexes of the plasma are apparently unduly stable, and it has been suggested that this is a persistence in the adult of the embryonic condition of the plasma.

Symptoms.—The disease usually manifests itself in early life, but not at birth, so that there is no excessive hæmorrhage from the cord. Severe bleeding at circumcision is common, and in 60 to 70 per cent. of recorded cases the disease was recognised before the second year. It is doubtful whether the bleeding is ever spontaneous, and there is no purpura, but excessive hæmorrhage may occur from a mere scratch, and great bruises or ecchymoses from trivial injuries. Some patients cannot use a tooth-brush on account of bleeding from the gums. Epistaxis is common, but internal bleeding is unusual, though hæmaturia, melæna and hæmatomyelia have been described. Trauma and dental extraction are the most usual causes of severe hæmorrhage, and a rick of the muscles which would pass unnoticed in an ordinary boy may lead to an extensive intramuscular hæmorrhage which leaves the patient exsanguinated. The bleeding is not so much severe as persistent; hence it is rare for the hæmophilic to die of a sudden profuse hæmorrhage, he rather fades out of life owing to the inability to stop the slow continued loss of blood.

The most remarkable form of hæmorrhage, and one which is common, is into the cavities of the joints. The joints which suffer most often are the knees and elbows, but any joints may be affected. The swelling and effusion take place with great rapidity, and with a great deal of pain. The joint is hot, tender, reddened, and the surrounding tissues swollen. The temperature is raised to 101° or 102° F. The effusion is almost pure blood, but as absorption proceeds it becomes a dirty brown colour, which stains the synovial membrane and the cartilages of the joint. It is sometimes absorbed rapidly, and the joint restored to complete mobility. When absorption is slow or effusions repeated, contraction and ankylosis may cripple the patient permanently. In a joint often affected, there is always considerable destruction of the cartilages and of the ligaments, with the result that the bones are exposed and undergo changes resembling those of osteo-arthritis. Osteophyte formation is, however, rare, and so is bony ankylosis. Fibrous ankylosis is, on the other hand, common. The spleen is not palpable. Hæmophiliacs are usually weakly individuals.

Diagnosis.—The diagnosis is based on the family history and on the delayed coagulation of the blood; the cytology and chemistry of the blood are normal. The joints are sometimes mistaken for tuberculous joints. A

more serious error is to incise a hæmatoma on the mistaken diagnosis of an

Prognosis.—It is said that less than 12 per cent. of hæmophiliacs survive to puberty, but the disease undoubtedly becomes less severe in later life, though still present. A peculiar feature of the disease is its variability, the blood at times clotting almost normally, at other times seeming almost incoagulable, and if the patient survives a severe hæmorrhage there is often a temporary improvement in the blood.

Treatment.—Treatment is unsatisfactory, and it is much better to try to stamp out the disease by discouraging the reproduction of affected families. The only members of a hæmophilic family who can safely beget children are the unaffected males. Sufferers from the disease should be protected from trauma as far as possible, and operations should be discouraged unless they are essential to life, in which case the patient should be transfused immediately beforehand.

For local treatment of a bleeding point, the loose clot should be washed away with hot water, and tampons soaked in normal serum or blood, or in a mixture of adrenalin and thromboplastin, should be firmly applied. Heat is a valuable agent and may be applied as hot water (42° C.), or, better, especially in hæmorrhage from an inaccessible cavity, as a stream of hot air. When a joint is distended with blood it should be aspirated; needle punctures rarely bleed much. The patient should be kept quiet, and morphine may be advisable. Transfusion is the best general treatment; other treatments recommended are injections of coagulen or hæmoplastin, cephalin by mouth, or applications of X-Rays to the spleen. Probably no treatment influences the diathesis, but courses of protein shock with T.A.B. vaccine or peptone may be tried, or serial injections of horse serum, 20 to 30 c.cm. every 2 months. Encouraging results have recently been reported from regular injections of ovarian extract (œstrin). Liver is quite useless.

3. MELÆNA NEONATORUM

Synonym.—Hæmorrhagic Disease of the Newly-born.

The bleeding in this disease is spontaneous, commencing at any time in the first week or two of life, most commonly on the third or fourth day. The bowel is the usual site of hæmorrhage, but blood may also ooze from the mouth, nose and urinary tract, or be extravasated into the viscera or the cavities of the body. Its incidence has been placed as high as 1 per cent. of all births, male and female, but its ætiology is quite unknown. Heredity seems to play no part. The blood platelets are normal, but the clotting time is greatly prolonged. If the disease is not immediately treated, death soon occurs from hæmorrhage and shock. In some cases acute gastric and duodenal ulcers have been found at autopsy, but it is more probable that these represent necrosed areas from submucous hæmorrhages than that they are the cause of the bleeding. For treatment, 10 to 15 c.cm. of human blood should be injected subcutaneously once or twice a day, when the bleeding usually stops quickly and the infant makes a good recovery. Horse serum can also be used. Other hæmorrhagic states may occur in the new born as a result of sepsis, syphilis, and more rarely thrombocytopenia and allied blood dyscrasias.

4. ESSENTIAL THROMBOCYTOPENIA

Synonyms.—Idiopathic Purpura Hæmorrhagica; Hæmogenia; Morbus Maculosus Hæmorrhagicus of Werlhof.

Definition.—A disease characterised by multiple hæmorrhages in the skin or from the mucous membranes, a reduced platelet count, a prolonged bleeding time, but a normal coagulation time.

Ætiology.—The disease occurs at all ages and in both sexes, but more commonly before puberty. Its pathology is very obscure. It has been suggested that the megakaryocytes in the bone-marrow are primarily diseased, but there is no convincing evidence of this. The remarkable alleviation of the symptoms after splenectomy is equally mysterious. The operation was introduced on the theory that the spleen was destroying an excessive number of platelets, but there are many facts which cannot be adapted to this theory: The bleeding may cease immediately the pedicle of the spleen has been tied, and before the platelets have had time to increase. The operation is usually followed by a great rise in the platelet count, but later the platelets may fall to subnormal levels without the recurrence of hæmorrhage. The platelet count and the bleeding time cannot always be closely correlated. There is much to suggest that the endothelial lining of the vessels is abnormal, and that the spleen may influence this. It is not known whether the disease is related to the hereditary hæmorrhagic diathesis, or whether constitutional factors are of importance.

Symptoms.—An acute and a chronic form are described. The acute form is uncommon. It begins suddenly and without warning, though sometimes there is a history of an acute infection a couple of weeks before. There is no pyrexia and the spleen is not palpable. Purpuric patches appear in the skin, of variable size and of irregular distribution. There is no erythema or whealing. Hæmorrhages occur from any of the mucosæ, the nose and mouth, the alimentary canal and the urogenital tract. The slightest injury gives rise to excessive bleeding, or the formation of large hæmatomata. The bleeding time is greatly prolonged, and the tourniquet test is positive. Examination of the blood reveals a thrombocytopenia, platelets being perhaps completely absent; there is usually a slight leucocytosis, and immature red cells and even normoblasts may be poured out to combat the anæmia. Recovery occurs in a few days or at most a few weeks, and the platelet count returns to normal. This may be the only attack, but in other patients a recurrence months or years later reveals that the disease is present in a relapsing form.

The chronic form of the disease, which accounts for 75 per cent. of the cases, may be of a continuous or of a relapsing type. In many cases the disease first manifests itself in childhood. In the continuous type there is persistent thrombocytopenia, with exacerbations of symptoms due to fluctuations of the platelets above and below the critical level of about 40,000 per c.mm., or to the effects of trauma or intercurrent infection. In the relapsing type there are long intervals of freedom during which the platelet count is quite normal. There may be persistent purpura, especially on the legs, or the parts exposed to trauma, or purpura may be completely absent. The spleen may be enlarged. There is a tendency for hæmorrhages to recur from the same site, as if it were an area of predilection, so that one patient

may suffer from hæmatemeses, another from hæmaturia, another from menorrhagia. In my experience the disease becomes less troublesome in later life, though the platelets remain at the same low level.

Diagnosis.—The diagnosis depends on the thrombocytopenia and the associated symptoms of platelet shortage, but it should be remembered that the platelets may be normal in the free intervals. For differential diagnosis the section on symptomatic hæmorrhagic states should be consulted; the absence of toxæmia and of joint pains is an important difference from these conditions and also from Henoch's purpura. Most difficulty will be experienced in distinguishing the acute form of essential thrombocytopenia from the purpura fulminans of infection, and from the purpura maligna of aplasia of the bone-marrow. In malignant thrombocytopenia there is usually leucopenia and no sign of regeneration of red cells. In the chronic form of essential thrombocytopenia it is rather easy to overlook the possibility of a hæmorrhagic disease altogether, especially when there is no purpura and the bleeding is always from one organ. On this account this diagnosis should always be considered in cases of symptomless hæmaturia, or hæmatemesis, or the like, or ill-advised operations may be performed.

Prognosis and Treatment.—Death may occur in the acute attacks, or irretrievable damage be done, as by hæmorrhage into the vitreous humour of the eye or into the central nervous system. Nevertheless the disease is relatively benign, and the physician should not allow his judgment to be impaired by the alarm that is always felt in the presence of a hæmorrhagic disorder. One of my patients had multiple cerebral hæmorrhages, in addition to external bleeding which made him profoundly anæmic. He was treated with transfusions and symptomatic remedies, as he firmly refused splenectomy, and he remained thrombocytopenic, anæmic and ill for several months. A year later he was perfectly well, working as a railway guard with a normal blood count. This is by no means an isolated example, and the natural tendency of the acute attacks is to recovery. The mortality of splenectomy in the acute attacks when the patient is bleeding is very high (80 per cent.), and on this account, and also because of the difficulty of diagnosis from infectious and malignant purpuras, the operation is rarely advisable in acute cases unless there is a clear history of previous attacks. In chronic cases, on the other hand, the value of splenectomy can hardly be exaggerated, the mortality is low (8 per cent.), and the disease is usually completely relieved. There is usually a critical rise in the platelet count after the operation, and though the platelets sometimes fall to subnormal levels again after an interval of weeks or months, recurrence of the bleeding is uncommon. There is no medical treatment, liver being of no value. Transfusion is of much value when bleeding is taking place, while the other methods described under hæmophilia may also be employed.

5. CONSTITUTIONAL HÆMOGENIA, OR THE HEREDITARY HÆMORRHAGIC DIATHESIS

Synonyms.—Hereditary Purpura Hæmorrhagica of Hess; Thrombasthenia of Glanzmann; Hereditary Pseudo-Hæmophilia.

This is a rare disease which bears much resemblance to essential thrombocytopenia, though its pathology is probably different. The symptoms are

identical with those of essential thrombocytopenia, the cardinal features being an increase in the bleeding time, and a tendency to purpura, spontaneous hæmorrhages, and excessive bleeding or bruising from trivial injuries. The coagulation time is normal and, therefore, such names as pseudo-hæmophilia are very ill chosen. It differs from essential thrombocytopenia in the following ways :

1. It is a hereditary disease. It is transmitted directly from generation to generation, and affects females twice as often as males (hence the term "female hæmophilia"). Sporadic cases also occur ("thrombasthenia").

2. The platelet count is reduced in only half the cases, and there is no close correlation between the number of platelets and the hæmorrhagic tendency.

3. Splenectomy has no effect on the disease, and is indeed a very dangerous operation.

It has been suggested that although the platelets may be normal in numbers they are defective in function in this disease (thrombasthenia), but there is little basis of fact for this. The mortality is fairly high, though the disease tends to improve spontaneously in adult life. No effective treatment is known, but arsenic has been used with apparent benefit. The disease has been frequently confused with hæmophilia, but while it is true that it is equally irremediable and almost as serious, the two conditions should be clearly distinguished, because not only the symptoms but also the eugenic prognosis is quite different, and unaffected members of thrombasthenic families may safely marry. The diagnosis is based on the family history and the signs of platelet insufficiency. In the present state of knowledge, sporadic cases in which the platelets are reduced in numbers will usually be diagnosed as essential thrombocytopenia, which may account for the occasional failure of splenectomy in that disease.

6. HENOCH'S PURPURA

Synonyms.—Anaphylactoid Purpura ; Hæmorrhagic Capillary Toxicosis ; Toxic Purpura.

Definition.—Although the term Henoch's purpura is sometimes restricted to cases characterised by purpura, colic and gastro-intestinal lesions, it is profitable to extend it to a group of non-thrombocytopenic purpuras, which are of obscure origin, and which may be accompanied by urticaria, œdema, swollen joints and various visceral manifestations. For this reason the milder cases which are known as purpura simplex, and also the poliosis rheumatica or arthritic purpura of Schoenlein are considered under this same heading, for all appear to be manifestations of the same pathological state.

Ætiology and Pathology.—The disease is related to allergic conditions, such as erythema multiforme, erythema nodosum, angioneurotic œdema and serum sickness. The lesions probably result from an abnormal permeability of the capillaries, which allow plasma and blood to escape through their walls. The sensitising agent is not always the same. In some instances it is the streptococcus, the attack following a sore throat, or persisting until a septic focus is drained. In other instances sensitisation to foods has been demonstrated, and the disease has been cured by removing them from the diet.

Symptoms.—The attack is usually preceded by symptoms of general bodily disturbance, such as headache, malaise, loss of appetite, and a rise of temperature. In the mildest cases (purpura simplex) a fine purpuric eruption appears, often affecting the limbs rather symmetrically, and with a special tendency to develop round the hair follicles. In severe cases there may be extensive, irregularly distributed ecchymoses, and there is much œdema of the face. Wheals and pemphigoid lesions may develop, and careful examination will often show that the purpura is not a pure hæmorrhage, but that it is raised or surrounded by a zone of erythema. Successive crops of purpura appear. Bleeding is not necessarily confined to the skin, but may be subperiosteal, intramuscular, or intravisceral. Joint pains are rarely absent, though the joints are seldom much swollen, and there may also be myalgia or neuralgia. The gastro-intestinal symptoms take the form of colic, bilious vomiting, and diarrhoea, with blood-mixed stools. The abdominal wall may be rigid, and it may be difficult to differentiate the lesion from an intussusception, which may indeed occur from invagination of a piece of intestine whose walls have been stiffened by the exudation of serum and blood. Similar lesions occur in the urinary tract, but extensive hæmorrhage from the mucosæ is rare. The spleen may be palpable and the urine may contain albumin, blood cells and casts. In rare instances death has occurred from cerebral convulsions, suggestive of acute uræmia; nephritis is, indeed, the most important complication.

The blood is normal, save for a slight anæmia or a mild leucocytosis. The platelets are normal or only slightly diminished, and the coagulation and bleeding times are normal. The tourniquet test may be positive, but in general there is little tendency to spontaneous or excessive external bleeding, and the mucosal hæmorrhages are small and attributable to oozing from areas of œdema and congestion.

Diagnosis.—The disease is not sharply divided from the symptomatic purpuras. It should, however, be clearly differentiated from essential thrombocytopenia and similar blood disorders by the absence of specific changes in the blood, and the presence of signs of toxæmia and increased capillary permeability. Cases with intestinal lesions may closely simulate intussusception, and they may occasionally be complicated by intussusception or peritoneal effusion.

Prognosis.—The disease tends to spontaneous recovery after an illness of a few weeks. Chronic and relapsing cases occur which are very troublesome, though rarely dangerous. The prognosis is good, except for complications, such as nephritis and intestinal obstruction.

Treatment.—Treatment should be symptomatic and conservative. Incautious attempts at desensitisation may aggravate the disease. Splenectomy is not indicated. In view of the risk of renal damage the patient should be at rest, the diet should be lacto-vegetarian, and the urine should be kept alkaline. No further treatment is necessary in the majority of cases. Chronic cases should be investigated for persistent infection, foci of sepsis, or evidence of protein sensitisation. Large doses of calcium are frequently prescribed, but it is doubtful if they have any value. Non-specific desensitisation may be attempted by subcutaneous injections of horse-serum, 10 to 20 c.cm. daily till improvement begins, or by minute doses of tuberculin.

7. HEREDITARY HÆMORRHAGIC TELANGIECTASIA

Definition.—A hereditary disease characterised by multiple telangiectases, which cause hæmorrhages from various sources, especially the nose.

Ætiology.—The disease is not strictly a blood disease, but a hereditary dystrophy of the capillary system, which is transmitted directly from generation to generation, affecting both sexes equally and behaving as a Mendelian dominant. It is, in my experience, at least as common as hæmophilia.

Symptoms.—Epistaxis generally begins in childhood and before any cutaneous telangiectases have been recognised, but it tends to become more frequent and severe with advancing years. The telangiectases are not present at birth, and are sometimes not noticed till middle life. They vary in kind, appearing as dilated venules, spider capillary networks, punctate red or purple spots and blebs, and raised nævi up to an inch in diameter. They are most common about the face, nose and mouth, and the trunk and limbs are generally spared, except for the tips of the fingers. Epistaxis is the common complaint, but external bleeding, hæmoptysis, gastrostaxis, hæmaturia, or cerebral hæmorrhage may occur. The blood is normal, except for the anæmia induced by the bleeding.

Diagnosis.—This depends on the family history and the presence of telangiectases, and both these may be missed if they are not sought for. Few telangiectases may be visible, and epistaxis or alimentary hæmorrhage may be the presenting symptom. Many cases are first seen by the rhinologist.

Prognosis and Treatment.—There is no curative treatment, and death from hæmorrhage occurs in a considerable fraction of the cases. Affected members of these families should, therefore, be strongly advised against having children, as half of their offspring will inherit the disease. Treatment of the nævi by cauterisation or radium is only moderately successful.

PROPHYLAXIS AND TREATMENT OF ANÆMIA

Prophylaxis.—A number of the diseases of the blood-forming organs, such as acholuric jaundice and hæmophilia, are pure hereditary dystrophies and rational treatment should be directed not to the individual but to the stock, all those who carry the morbid trait being advised against reproduction. In other diseases, such as pernicious anæmia, heredity plays a notable part, but in the present state of knowledge it is difficult to give eugenic advice. Members of affected families who have achlorhydria would be wise at any rate to limit their families. Prophylaxis of the acquired forms of anæmia is not often feasible, but the relation of anæmia to nutritional disturbances should be emphasised and especial care should be taken in the growing periods of life, childhood and pregnancy, that the diet contains a sufficiency of iron and protein.

Treatment.—Good treatment is not possible without exact diagnosis, and if a patient is ill enough to be treated for anæmia, then he or she is ill enough for an examination of the blood to be necessary. It is surprising how often debility is mistaken for anæmia, but the distinction is often difficult on clinical examination. Much time and money are wasted by the prescription of remedies which are not indicated, and the physician is confused and

unable to evaluate the effects of treatment. It is a simple matter to test the hæmoglobin, after which a more detailed examination of the blood can be advised if anæmia is found. Many disturbances of the blood are of a highly specific nature, and the appropriate treatment can only be elucidated by careful clinical and hæmatological study. It is no use prescribing iron for the anæmia of scurvy, or vitamin C for the anæmia of myxœdema.

Symptomatic disturbances of the blood-forming organs, which are far commoner than their primary diseases, usually recover spontaneously if the cause can be removed; if it cannot, they rarely respond well to symptomatic treatment. Many remedies for anæmia have gained an unfounded reputation by being administered to patients who would have recovered equally rapidly without treatment. It is surprising, for example, how swiftly the blood may be regenerated after a severe hæmorrhage. On the other hand, in chronic and persistent anæmias the dosage of the drugs which are useful in treatment is much higher, and the period necessary for treatment is much longer, than is often realised. By ordinary methods of examination little improvement may be detected in the first fortnight, though reticulocyte counts will reveal that numbers of new cells are entering the blood stream. Patients who are severely anæmic should be confined to bed, for this makes a great difference to the speed of regeneration of the blood. A generous mixed diet should be given, rich in vitamins, and liver or kidney should be taken two or three times a week. Fresh air and sunshine or ultra-violet therapy, also improve the patient's condition, but too much should not be expected from these ancillary treatments, which by themselves will rarely influence a severe anæmia.

Iron is of value in the majority of anæmias of low colour index, especially those which are due to chronic hæmorrhage, or to defective absorption of iron (idiopathic hypochromic anæmia). Recent studies have shown that the various preparations of iron differ greatly in their activity. Elemental iron, as in ferrum redactum, is rather inactive, on account of its insolubility. The ferrous salts are the most active, next the scale preparations, and then the ferric salts; organic preparations of iron, such as hæmoglobin, in which the iron is "masked," have no therapeutic activity. Colloidal preparations of iron have no advantages, as they are probably precipitated at once in the stomach. I use only two preparations of iron: Bland's pill (ferrous carbonate), which must be fresh and is often best prescribed as a powder, in a dosage of 10 to 15 grains thrice daily after food; and iron and ammonium citrate, in a fluid mixture, 20 to 40 grains thrice daily after food. Intolerance of iron is very unusual, and is usually due to suggestion; the digestion improves in most cases, and with large doses diarrhœa is a more common complaint than constipation. Menorrhagia sometimes occurs, especially in women about the menopause, and may require special treatment. Iron should not be given by injection. The majority of ampoules of iron preparations which are sold contain infinitesimal amounts of the metal, and are ineffective; potent preparations cause much pain, and the injections may lead to iron poisoning—headache, vomiting, paralysis and even death. A patient too ill to take iron by mouth should be transfused.

Liver and stomach are often prescribed as if they were a panacea for all forms of anæmia, but in my experience they are of no value except in the small and well-defined group composed of pernicious anæmia and allied

megalocytic anæmias. At present there is a host of preparations on the market, which vary greatly in price and activity. I have found desiccated stomach prepared by Wilkinson's method to be cheaper, more active and better tolerated than either raw liver or liver extracts; the dose is $\frac{1}{2}$ oz., twice daily. Fluid extracts of liver are more palatable than dry, and they should be given in a dose equivalent to from $\frac{1}{2}$ lb. to 2 lb. of liver a day. Treatment should be guided by the blood count and the symptoms. The blood should be maintained at 5 million red cells per c.mm. and 100 per cent. hæmoglobin, and it should be examined at intervals to ensure that this level is maintained. Whatever the level of the blood count, paræsthesiæ or similar nervous symptoms indicate that enough effective substance is not being given. I am convinced that subacute combined degeneration in the early stages can always be arrested by adequate treatment. Infection and old age both increase the dosage necessary for the control of pernicious anæmia. It has been well said that the daily maintenance dose is "not some liver, but enough liver for the given case." Extracts for intramuscular injection are now available, and are of the greatest value in emergencies.

Hydrochloric acid is of value in the treatment of the dyspepsia of simple achlorhydric and pernicious anæmia, but it has no effect on the anæmia. Heroic doses are unnecessary, 20 to 30 minims of the dilute acid at meal-time being sufficient. If desiccated stomach is used, hydrochloric acid is not usually required.

Arsenic is a drug which was formerly administered in all forms of anæmia, but its use is now becoming restricted to leukæmia. It is probable that arsenic and X-Rays have an identical action, which is to stimulate the maturation of the immature cells in the bone-marrow. It is usually administered as Fowler's solution of potassium arsenite, beginning with 2 minims and increasing to 10 to 15 minims thrice daily, after meals, until the desired effect is produced, or signs of intoxication begin to appear. The drug is then discontinued for 4 to 6 days, and resumed in a smaller daily dosage, the maintenance dose being determined by the clinical condition and the blood picture.

Transfusion is essentially an emergency measure, and it has little curative value except in the rare hæmolytic anæmia of Lederer. It has a definite mortality, and should be advised with as much circumspection as a surgical operation. It is indicated when the patient is too ill to react to curative treatment, or when it is necessary to bring him into condition for treatment directed at the cause of the anæmia. The very greatest care should be taken, fresh sera always being employed for the grouping, and a direct compatibility test being carried out immediately before transfusion. Donor and recipient should always belong to the same group, for experience has shown that members of Group IV. cannot safely be employed as universal donors. Under ordinary conditions the advantages of working with citrated blood outweigh any theoretical disadvantages; the blood should be kept warm and should be administered slowly. Even when every care is taken reactions occur, especially in febrile patients. The anaphylactic type of reaction occurs during or immediately after the transfusion. It is characterised by dyspnœa, cyanosis, swelling of the face, and urticarial rashes, and it responds to treatment by adrenalin or morphine. The hæmolytic type

of reaction may occur during the transfusion, or some hours later. It is characterised by tingling pains in the veins, precordial oppression, cyanosis, rigors, high fever, hæmoglobinuria and jaundice ; death may occur at once, or later from suppression of urine. It has been shown that suppression of urine will not occur if the urine is dilute and alkaline, and it is therefore advisable to prescribe fluid and alkalis for 24 hours before and after a transfusion.

L. J. WITTS.

SECTION XII

DISEASES OF THE SPLEEN

A SATISFACTORY classification of diseases of the spleen cannot as yet be made, partly because it is uncertain in many cases of splenic disease whether the organ is diseased primarily or secondarily, and partly because it is not yet established upon which constituent structure of the organ several of the disease-processes which affect it fall. The spleen is involved in a very large number of general diseases, so much so that enlargement of the organ comes to be a matter of great frequency and also of great importance.

ENLARGEMENT OF THE SPLEEN

The recognition of an enlarged spleen turns upon the discovery of a tumour in the left hypochondrium, lying anterior rather than posterior to the lateral sagittal line, descending with inspiration, possessing a thin inner margin and a thicker outer margin. The most diagnostic point is the palpation of one or more notches on the inner margin. The thoracic splenic dullness, in health occupying a small area about the level of the ninth rib in the mid-axillary line, is enlarged upwards. If the enlarged organ extends as far as, or below, the navel, the tumour tends to transgress the mesial line, so that its "march" takes a direction towards the right iliac fossa. The differential diagnosis is chiefly from a renal (or suprarenal) mass. The latter tends to lie more posterior, so that it is felt more easily in the loin. When it is a massive tumour, however, an enlarged kidney may cause eversion of the lower ribs anteriorly, a sign which is rarely produced by a splenic tumour, however large. A band of resonance, due to the descending colon, can sometimes be made out crossing a renal tumour, but in the case of an enlarged spleen such resonance, if present, lies mesial to the mass. Gastric carcinoma occasionally simulates splenic enlargement: the diagnosis is to be made by X-Ray examination of the stomach. Enlargement of the left lobe of the liver, disproportionate to enlargement of the right lobe, is sometimes another difficulty.

The spleen is often found to be enlarged at autopsy when the organ was not palpable during life: the cause is usually acute sepsis, or severe typhoid fever, and the softness of the organ precludes its discovery by palpation. If suspected, special care should be given to percussion (v.s.).

The causes of enlargement of the spleen are: (1) Acute general infections, especially the typhoid group, septicæmia and undulant fever. (2) Septic

endocarditis. (3) Chronic infections, especially tuberculosis, syphilis and Hodgkin's disease. (4) Protozoal infections, especially malaria and kala-azar. (5) Blood diseases, such as "splenic anæmia," leukæmia, Vaquez' disease (erythræmia), acholuric jaundice and pernicious anæmia. (6) Mechanical obstruction to the venous return from the organ, as in portal cirrhosis of the liver, thrombosis of the portal or splenic vein, and in some cases of decompensated cardiac disease. (7) New formations, *e.g.* cysts, neoplasms, amyloid disease, Gaucher's disease. (8) Ptosis and dislocation of the organ; the cause of the enlargement in these cases is probably passive congestion. Splenomegaly is sometimes found without assignable cause.

Perisplenitis occurs in a number of diseases in which splenic enlargement is a feature. Perhaps the most common diseases are septic endocarditis, Vaquez' disease, leukemia and acholuric jaundice. Pain is the chief symptom, and friction, both audible and palpable, is the diagnostic sign: both are prone to be mistaken for pleurisy. Friction is sometimes found over an enlarged spleen when there is no pain, and perisplenitis is probably the cause, in not a few cases, of pyrexial attacks in association with enlargement of the organ, of whatever nature.

SPLENIC ANÆMIA

Synonym.—Banti's disease.

Definition.—A chronic disease characterised by splenomegaly, anæmia of the "chlorotic" or "secondary" type, with leucopenia, and a tendency to hæmorrhage, especially from the stomach. In many cases there is a later tendency to the development of cirrhosis of the liver associated with ascites and jaundice (Banti's disease).

Ætiology.—The syndrome just defined is still regarded as a primary disease of the spleen (! reticulo-endothelial structure) by most authorities, and, in the absence of any knowledge of its cause, this is at least as convenient as placing the disease elsewhere in nosology. That the diseased spleen is a very important, if not the primary, ætiological factor is borne out by the fact that splenectomy provides, in most cases, that have not advanced to the stage of hepatic cirrhosis, a dramatic cure. Moreover, in some cases it may be clearly demonstrated that the splenomegaly precedes the anæmia by some months or even years. The current view of the essential causative factor is that it is an intoxication of unknown nature.

The *incidence* of the disease is probably somewhat greater than was formerly supposed. A familial incidence has been noted. Males appear to suffer much more than females. The majority of patients come under observation between the twentieth and fortieth years, but as the disease tends to be very chronic, it is met with at most ages after the late teens:

Pathology.—The enlarged spleen often yields evidence of old perisplenitis, and adhesions are fairly common. Naked eye appearances on section are not characteristic. The histological changes are those of general fibrosis with capsulitis and hyperplasia of the spleen pulp, most marked in the Malpighian bodies. The endothelial lining cells of the blood spaces also show hyperplasia. Hæmorrhages may be present.

In post-mortem examinations made in cases that are old-standing, the

liver frequently shows cirrhotic changes. These are both interlobular and portal in distribution. The bone marrow shows proliferation, as in many forms of chronic anæmia.

Symptoms.—The *splenomegaly* is constant. It is very variable in degree, from a tumour that extends but a handbreadth below the left costal arch to a mass occupying the greater part of the left, and a considerable portion of the right, side of the abdomen. In its texture it is firm, and in its contours it is smooth and uniform. As already stated, the splenomegaly may precede the other symptoms and signs of the disease by several years.

The *anæmia* has no characteristic features: it is of the "secondary" type: red cells reduced, hæmoglobin reduced still further, yielding a low colour index, and a leucopenia, *i.e.* a low total white cell count, with disproportionate reduction in the polymorphonuclear cell. A common count is R.B.C. \pm 2,500,000, H.B. \pm 30 per cent., C.I. 0.6, W.B.C. \pm 4000.

HÆMORRHAGES.—The most common is hæmatemesis, varying in degree and frequency. It occurs in more than half of all cases. Mæna may be present without hæmatemesis. A copious hæmatemesis may cause a severe exacerbation in the anæmia, and, as in any large loss of blood from the portal area, the enlarged spleen may be considerably reduced in size thereby. Other forms of hæmorrhage, such as purpura and epistaxis, are relatively uncommon.

Other symptoms and signs include a facies which is helpful in diagnosis: a pallor combined with a slight olive tint which has been by some termed a slight bronzing or pigmentation, and, when the liver is involved, ascites and jaundice. The anæmia brings its own chain of symptoms: œdema of the ankles, dyspnoea on exertion, hæmic bruits and slight albuminuria.

Course.—This covers several, it may be many, years. Remissions occur. If radical treatment be not undertaken, death occurs from asthenia with cardiac failure, severe hæmorrhage or, in a certain proportion of cases, hepatic insufficiency.

Diagnosis.—This is from Hodgkin's disease, cirrhosis of the liver with splenomegaly, atypical leukæmia, diseases of the splenic or portal veins and pernicious anæmia with splenomegaly.

If the spleen is conspicuous by its enlargement, and lymph-node involvement is inconspicuous, there may be some difficulty for a time in marking off lymphadenoma from splenic anæmia. But the "abdominal type" of Hodgkin's disease is amongst the least chronic forms of lymphadenoma, and developments which are decisive are likely to take place within a few months.

Splenomegaly may be present in all forms of cirrhosis of the liver—portal, Hanot's, syphilitic and the cirrhosis associated with hæmochromatosis. In portal cirrhosis, the facies is important, the patient is usually alcoholic, there are symptoms of chronic gastritis, and evidence of collateral portal circulation is usually present. Anæmia is not a feature, unless it be at the last stages of the disease. Ascites does not occur in splenic anæmia, except during the stage which is now usually designated Banti's disease. During the "aleukæmic" stages of leukæmia the diagnosis from splenic anæmia may be difficult, but in the former disease the differential white blood count is usually abnormal and there are generally marked changes in the red cells. Pernicious anæmia may usually be differentiated by the blood picture, by a Price-Jones curve, and by the therapeutic effect of liver feeding.

Treatment.—The effect of *splenectomy*, as already said, is almost uni-

formly good if undertaken before cirrhosis has occurred in the liver and if the general condition of the patient is not too bad at the time of the operation. Even if fibrosis has begun in the liver, this should not be a bar to the operation, as cases have been seen to undergo arrest even after demonstrable cirrhosis is present. Should the anæmia be very marked, and response to hæmatinic measures (iron, arsenic, full dietary, fresh air, sunlight, etc.) prove unsatisfactory, one or more transfusions of blood should be given prior to the operation.

X-RAY TREATMENT.—Irradiation of the spleen gives good temporary results in many cases, but this method should only be used if it is decided that splenectomy will not be indicated later. The reason of this is that X-Ray applications tend to induce fibrosis of the organ and also adhesions, and the latter are apt to render splenectomy difficult and dangerous.

GAUCHER'S DISEASE

Though, strictly speaking, this is a general disease, the splenomegaly that accompanies it is such a marked feature that it is usually described in this place. Special attention has been directed by pædiatrists towards the disease of late years. It occurs in children, is familial in character, and is associated with a secondary anæmia and hæmorrhages. The pathology of the disease is obscure, but the essential lesion consists of a deposit of a lipid material in the reticulo-endothelial tissues all over the body. The diagnosis has, in some cases, been made by splenic puncture, the characteristic Gaucher cells being demonstrated in the splenic pulp thus removed. No radical method of treatment is known.

HORDER.

SECTION XIII

DISEASES OF THE CIRCULATORY SYSTEM

DISEASES OF THE HEART AND PERICARDIUM

It is generally recognised that within recent years there has been a great advance in our knowledge of cardiac disorders, and this advance has been of so practical a character, and of such vital importance in the diagnosis, prognosis and treatment of these diseases, that it is the duty of every clinician to make himself acquainted with its nature and scope. This progress has been mainly due to the introduction of what are called graphic methods in the examination of the cardiac mechanism. By means of the electro-cardiograph and the clinical polygraph we are now able to analyse the cardiac action in a manner which was never possible before. The work of elucidation having been accomplished, it is, however, not now necessary to employ either of these instruments in the great majority of cases, the use of a sphygmograph being sufficient, and in a large proportion palpation and auscultation suffice. This is of great practical importance to the general practitioner.

As the electro-cardiograph cannot be regarded as an instrument available to the general practitioner, I have included clinical electro-cardiography at the end of the section.

PHYSIOLOGICAL CONSIDERATIONS

THE APEX-BEAT.—The movement of the heart at each contraction is communicated to the chest wall and can be seen and felt over a limited area. In normal circumstances it is the left ventricle which gives rise to the clinical apex-beat, and the apex-beat may then be defined as that part which is farthest to the left at which a definite forward thrust is imparted to the finger held perpendicularly to the chest. When the right ventricle is much enlarged, however, that chamber may displace the left ventricle backwards, so that the apex-beat is due to the contraction of the right, instead of the left, ventricle.

SINO-AURICULAR NODE.—The *sino-auricular node* is a node of specialized tissue which is situated at the junction of the superior vena cava with the right auricle. In it are nerve fibres and ganglion cells, which are connected with the vagus and sympathetic nerves. The *auriculo-ventricular node* is a small node of specialized tissue which is situated in the septal wall of the right auricle. The *auriculo-ventricular bundle* is a bundle of tissue connecting the auricles and ventricles. It arises from the auriculo-ventricular node,

passes forwards in the interauricular septum, then turns downwards, and at the upper margin of the interventricular septum divides into two branches, the right and left septal divisions, one of which goes to the right and the other to the left ventricle, each ending in the ventricular musculature by widespread subendothelial arborizations—the Purkinje fibres. Nerve-fibres and ganglion cells are present in the auriculo-ventricular bundle, and its blood supply is mainly derived from a special branch of the right coronary artery.

FUNDAMENTAL FUNCTIONS OF THE HEART MUSCLE-FIBRES.—There are five fundamental functions of the fibres of the heart muscle, namely, stimulus production, excitability, conductivity, contractility and tonicity—contractility being the most important. These functions may be defined as follows: By stimulus production is meant the power which the muscle-fibres possess of originating a stimulus which can excite the heart to contract; by excitability is meant the power to receive a stimulus; by contractility is meant the power of contracting when stimulated; by conductivity is meant the power of conveying a stimulus from fibre to fibre; and by tonicity is meant that function of the heart muscle which keeps the heart during diastole in a state of slight tonic contraction.

The remains of the primitive cardiac tube are more excitable than the auricular or ventricular tissue, and the remains of the sinus venosus at the orifices of the great veins are the most excitable part. The stimulus for contraction, therefore, arises normally at this point, and there is reason to believe that it begins in the sino-auricular node; for this reason the node has been called the “pace-maker” of the heart; the rhythm of the sinus governs the rhythm of the remaining segments of the heart.

From the sino-auricular node, the stimulus for contraction travels to the other portions of the heart by means of the function of conductivity. It first spreads over the auricles, and auricular systole takes place. It is then conveyed through the auriculo-ventricular node, along the auriculo-ventricular bundle, its two main branches and their subendothelial arborizations, and is so distributed to the ventricles. Normally, therefore, stimulation and contraction of the sinus, the auricles, and the ventricles occur in the order named, the ventricle contracting only in response to stimuli received from the auricle through the auriculo-ventricular bundle. It is scarcely necessary to point out that relaxation proceeds in the same order as contraction. When the stimulus for contraction arises in the sinus part of the auricle, we speak of normal or sinus rhythm.

While normally the stimulus for contraction of the heart arises in the sinus part of the auricle, if any other portion of the primitive cardiac tube become more excitable than the sinus, the stimulus arises at that particular point; for this reason the different parts of the heart are capable of starting an independent contraction. When the stimulus for contraction arises at some site other than the sinus part of the auricle, *i.e.* at an abnormal point, we speak of abnormal rhythm. The stimulus may arise in the auricle, or in the auriculo-ventricular junctional tissues—either the auriculo-ventricular node, or the auriculo-ventricular bundle above its division into two branches—or in the ventricle, below the division of the auriculo-ventricular bundle. In what is termed “nodal rhythm” the stimulus for contraction arises in some part of the auriculo-ventricular junctional tissues, giving rise to a simultaneous contraction of both auricle and ventricle. When the ventricles

beat independently of the auricles, the independent rhythm of the ventricle is called "idio-ventricular" rhythm.

The rate at which the wave of contraction travels from fibre to fibre varies in different parts of the heart. Thus, the impulse spreads in the auricles and ventricles more quickly than it does from auricle to ventricle. Nevertheless, the impulse travels so rapidly that the contraction of the ventricle commences almost immediately after the completion of the auricular systole. The interval separating the commencement of auricular and ventricular contraction is of great clinical importance, for it is an index of the time-relations of the contraction of the auricles and ventricles, and of the function of conductivity of the auriculo-ventricular bundle above its division into two branches. It is called the *As-Vs interval*. The function of conductivity of the heart may be measured by means of the clinical polygraph, and the electro-cardiograph.

The function of excitability also is most highly developed at the sinus part of the auricle. The rate of the heart depends upon the functions of stimulus production and excitability, an increase of their activity resulting in an increase of the frequency of the cardiac action. The activity of the function of stimulus production varies a good deal, as, for instance, the slight acceleration of the heart-rate during inspiration, and the corresponding slowing which occurs during expiration, in the young. When excitability is increased, the heart has also a greater tendency to respond to abnormal or irregular stimuli; hence extra-systoles are more likely to occur. While diminished excitability may lessen the heart-rate, it should be remembered that slowing of the ventricular rate may be due to other causes, such as depressed conductivity. When stimulus production and excitability are equal, the rhythm of the heart is regular.

Immediately after the muscle-fibres of the heart have contracted, they cannot again be stimulated; in other words, excitability has for the moment disappeared. This is called the refractory stage. Restoration of excitability, however, at once recommences, and steadily increases during diastole. When stimulated, the cardiac muscle either does not contract at all, or it contracts to the fullest possible extent at the time, whether the stimulus be weak or strong; it is a case of "all or none." The longer the time that has elapsed since the previous contraction, the weaker is the stimulus required to bring about a further contraction. Further, the greater the degree of excitability of the muscle-fibres, the weaker is the stimulus required, and the earlier in the refractory period will the heart contract. The amount of contraction does not depend upon the strength of the stimulus employed, but varies according to the time at which the stimuli are applied. When a contraction occurs early in diastole, the contraction in the succeeding cardiac cycle is weaker than that preceding it. Within certain limits, the degree of contractility depends upon the length of the preceding diastole; the greater the period of rest, the more perfect and full is the recovery. It can, therefore, be readily understood that the greater the heart-rate the greater is the possibility of cardiac failure. The circulation is carried on most efficiently when the cardiac rate is exactly that which allows the myocardium to recover its full contractility, a rate over or under this being a disadvantage. Similar laws apply to each of the other special functions of the heart muscle. In the case of conductivity, for example; when conduction occurs, this function

has been exercised to the fullest extent possible at the time of stimulation. The refractory period follows immediately after the conduction of a stimulus, and during this brief period the muscle-fibres cannot again conduct a stimulus, conductivity being completely exhausted. Restoration, however, quickly commences, and ultimately the function is restored. The extent of the relaxation between the contractions depends upon the degree of tone present, and upon the rate of the heart-beat. With a slower rate, there is, of course, more time for full relaxation. There should be a sufficient period of rest after each function has been exercised. Within certain limits, the greater the period of rest the more perfect and full is the recovery of each special function. In heart failure one or more of the five fundamental functions of the fibres of the heart muscles are at fault, and, if this occur to two or more simultaneously, the different functions are not necessarily equally affected. From what has been said, the value of rest in heart failure can be readily understood.

The *pulsus alternans* is probably an indication of depressed contractility of the heart. When conductivity of the heart is diminished there is some degree of heart-block. A lowered state of tonicity results in dilatation of the heart and of the auriculo-ventricular orifices.

The heart has the power of rhythmically contracting and dilating, due to an inherent power possessed by the cardiac musculature, independent of any extrinsic nervous influence. Nevertheless, the activity of the various functions of the muscle-fibres is under nervous control. Both the inhibitory fibres of the vagus and the accelerator fibres of the sympathetic are normally in a state of tonic activity, and the cardiac centres are in a state of continuous slight excitation.

There are reasons for believing that, besides decreasing the rate of the heart, the vagus nerve depresses the functions of excitability, contractility, conductivity—either by acting on the auriculo-ventricular bundle, or by diminishing the irritability of the ventricle itself—and tonicity; and that the accelerator nerve, besides increasing the rate of the heart, increases the force of contraction and conductivity. Stimulation of the central part of the divided vagus nerve is followed by a fall of blood-pressure, and simultaneously by a retardation of the beats of the heart. Inhibition of the heart is due to stimulation of the vagus as a diastolic effect; acceleration is due to stimulation of the sympathetic as a systolic effect.

THE CARDIAC CYCLE.—Stated briefly, in the cardiac cycle there occur in rapid succession auricular systole, ventricular systole, and ventricular diastole. The auricular diastole commences during the ventricular systole, and the ventricular diastole continues during auricular systole. The diastole of the auricles coincides with the commencement of the ventricular systole, the diastole of the ventricles with the commencement of the pause. The two active phases (systole and diastole) are followed by the state of rest.

There are three phases in the systole of the ventricles, namely: (a) The period during which all four valves are closed; this is called the pre-sphygmic period. The pressure within the ventricles has caused the auriculo-ventricular valves to close, but it is not yet greater than that in the aorta and pulmonary artery, so that the semilunar valves remain closed. (b) The period during which the semilunar valves are open; this is called the sphygmic or pulse-period. The pressure within the ventricle having risen above that in the

aorta and pulmonary artery, the semilunar valves are forced open and the blood flows from the ventricles into these vessels. (c) The period between the closure of the semilunar valves and the opening of the auriculo-ventricular valves; this is called the post-sphygmie period. It should be noted that the sphygmie or pulse-period in a tracing of the cardiac apex, carotid pulse or radial pulse, does not refer to the actual time of occurrence of ventricular systole, but to a period in the tracing; and, on account of the distance from the heart, the sphygmie or pulse-period will necessarily be later in a radial tracing than the same period in a tracing taken at the cardiac apex or over the carotid. The periods of time which elapse between the apex-beat and the carotid pulse, and between the carotid and radial pulses, have each been found to be $\frac{1}{10}$ th of a second; the pulse-period, therefore, in a radial tracing commences about $\frac{1}{10}$ th of a second behind the same period in a tracing of the carotid, and about $\frac{1}{5}$ th of a second behind that in a cardiogram.

Assuming that in normal health the human heart beats about 72 times per minute, each cardiac cycle, therefore, is completed in about $\frac{5}{6}$ ths of a second, this time being divided up in the following manner: systole of auricle, $\frac{1}{10}$ th of a second; systole of ventricle, $\frac{3}{10}$ ths of a second; diastole, $\frac{4}{10}$ ths of a second. The most stable part of the cardiac cycle is the ventricular systole, and the most variable is the diastole. The rate of the heart-beat mainly depends upon the duration of the diastole. When the heart beats unusually quickly, the duration of the diastole is shortened by a greater degree than that of the systole; in other words, when the period of the cardiac cycle decreases it is the long pause which is particularly shortened.

THE CLINICAL POLYGRAPH

By means of the clinical polygraph the movements of both auricles and ventricles can be recorded graphically, the time-relations of their contractions studied, and the function of conductivity of the auriculo-ventricular junctional tissue measured. It was by means of the clinical polygraph that the various forms of irregular action of the heart was first investigated and classified. It is possible to identify sinus arrhythmia, the various types of extrasystoles, the various degrees of heart-block, the pulsus alternans, auricular fibrillation, and a proportion of cases of auricular flutter. At the present time, however, the clinical polygraph has largely been superseded by the electro-cardiograph in clinical practice, since the latter instrument gives all the information to be obtained by the polygraph, its findings are more accurate, and it provides additional information of the condition of the myocardium.

By means of the clinical polygraph it is possible to obtain tracings of any two of the following: The radial or brachial pulse, the apex-beat, the carotid pulse, the liver pulsation, and the respiratory movements. A time-marker registers $\frac{1}{5}$ th of a second on the recording surface. For clinical purposes, it is usual to take simultaneous records of the radial or brachial pulse, and of the pulsation of the jugular vein at the root of the neck. A tracing of the radial pulse is called a sphygmogram or arteriogram, and a tracing of the venous pulse is called a phlebogram.

0.2 seconds (Fig. 23). If it exceeds $\frac{1}{8}$ th second, it indicates depressed conductivity by the auriculo-ventricular junctional tissues (Fig. 35).

In cases of great distension of the right auricle the *c* and *v* waves coalesce to form a plateau-shaped wave (Fig. 25). This was described by Mackenzie

FIG. 25.— Simultaneous tracings of the jugular and radial pulses, from a case of auricular fibrillation, showing the ventricular form of venous pulse, and an unusually slow radial pulse.

as the ventricular form of venous pulse when it occurred in the absence of the *a* waves, but the condition is due to the great distension rather than to auricular fibrillation.

Polygrams of the various types of irregular action of the heart will be found under their respective headings.

HEART FAILURE

In considering heart disease it is of fundamental importance that we should have a true conception of the principles which underlie heart failure. It should be understood that the essential cause of cardiac failure lies in the heart muscle, and is due to changes in the heart muscle which render it unable to maintain an efficient circulation, one or more of its five fundamental functions being impaired. Now, if this view of the causation of heart failure be correct, valvular defects, diseased conditions of the blood vessels, and disturbances of the cardiac mechanism—such as auricular fibrillation—should be regarded from the point of view of the relation which they bear to the myocardium, rather than as specific affections in themselves. Let us take the case of a valvular lesion: First of all, it can be readily understood that it is a mechanical impediment to the heart-muscle in its work. But it should always be remembered that there are, as a rule, along with the valvular lesion, coincident changes in the cardiac musculature, or the blood vessels, or both. In all cases of chronic valvular disease, therefore, it is of the utmost importance that we should endeavour to ascertain whether the lesion which has invaded the valve has also affected the myocardium, or the blood vessels, or both, and if so to what degree.

These morbid changes may occur as an acute condition, which later on becomes chronic; or as a primary chronic affection. As an example of the former, acute simple endocarditis in early life may be cited. It is recognized that this is usually followed by organization, resulting in the formation of fibrous tissue, which tends to contract, ultimately giving rise to permanent

stenosis, or incompetence, or both. It is also known that in every case of acute endocarditis there is probably always present some degree of myocarditis. But it is not sufficiently understood that acute myocarditis is often followed by chronic interstitial myocarditis, which, as in the case of acute endocarditis, may not fully declare itself until some years later. We should always try to ascertain whether there is coincident chronic interstitial myocarditis and if so its degree.

As an example of a primary chronic affection may be cited primary chronic endocarditis, more commonly of the aortic valve, which comes on insidiously during or after middle life. As a rule there are coincident or secondary changes in the cardiac musculature, the aorta, or the coronary or other arteries. Here also it is our duty to ascertain whether any of these changes are present, and, if so, in what degree.

Another point of great importance is whether the morbid affection (valvular, myocardial or vascular) is progressive or not. In this connexion it may be mentioned that primary chronic affections show a greater tendency to be progressive than those changes which follow an acute inflammation.

By the "rest force" of the heart is meant the force inherent in the heart-muscle of maintaining an efficient circulation when the body is at rest. By the "reserve force" of the heart is meant the force inherent in the heart-muscle which is called upon when bodily effort is made.

The "reserve force" of the heart is of the utmost importance. It may be estimated by the response of the heart to effort. This includes: (1) The effect of a standard piece of physical exertion on the cardiac and respiratory rates, which is called the "exercise tolerance" test. The pulse-rate should not be unduly increased, and it should return to its former rate within two minutes after the cessation of the exercise. (2) That which is of much greater value, the amount of physical exertion in which the patient can indulge without experiencing undue shortness of breath, undue palpitation, undue fatigue, giddiness, faintness, discomfort or pain, or a sense of constriction in the chest.

The natural standard of the heart's strength and also the functional efficiency of the organ depend upon its reserve force. It should be remembered that the former varies in different healthy individuals. Each individual knows the amount of exertion in which he can *normally* indulge without producing symptoms of cardiac distress, and also is aware when there is a departure from this, and to what extent. Our inquiry should aim at finding the normal standard of a patient, whether it has decreased, and if so, to what extent. It is necessary to point out that a departure from the normal standard of an individual may be due to temporary or extrinsic causes, such as deficient tone due to lack of physical exercise, temporary physical or mental overstrain, anæmia, chronic bronchitis, and emphysema.

Inquiry should also be made whether any departure from the normal standard is increasing, and, if so, whether in spite of an adequate period of rest and the employment of other remedial measures.

By heart failure is meant the condition in which the heart-muscle is unable to maintain an efficient circulation when bodily effort is made.

Cardiac failure almost invariably begins with a diminution of the reserve force of the heart. This manifests itself by a limitation of the area of cardiac response, *i.e.* an individual cannot indulge in the amount of physical exertion

which formerly he was able to do without experiencing symptoms of cardiac distress. These symptoms may appear as the result of less and less effort, until ultimately the "rest force" is diminished, some or all of the symptoms being present even during rest, and objective signs also become evident.

At this stage we would point out that when endeavouring to ascertain whether cardiac failure is present or not, and, if so, its degree and whether it is progressive, while the results of clinical and instrumental examination are of great importance, the most important question of all is the functional efficiency of the heart. Is this impaired, and, if so, to what extent, and is the degree of impairment increasing? The best way to answer this question is to ascertain how the heart responds to effort.

The word "compensation" and "decompensation" are sometimes used with reference to heart disease. When in valvular disease dilatation is not in excess of hypertrophy, we have what is termed full or perfect "compensation." In these cases the reserve force of the heart is not diminished. When dilatation is in excess of hypertrophy, we have "decompensation" or failure or loss of "compensation." In these cases there is a diminution of the reserve force and, it may be, of the "rest force." While the terms "compensation" and "decompensation" are not strictly synonymous with those of absence of, and presence of, cardiac failure respectively, for practical purposes they correspond.

The commonest symptoms of cardiac failure are breathlessness, palpitation, fatigue, giddiness, faintness, discomfort or pain, or a sense of constriction in the chest, on exertion.

1) Breathlessness or dyspnœa is one of the earliest, and a very important symptom of cardiac failure, the amount of exertion which the patient can undergo without experiencing shortness of breath being of great value in estimating the state of integrity of the heart muscle. It should be borne in mind, however, that dyspnœa on exertion is a symptom common to many affections besides heart disease, such as anæmia, broncho-pulmonary affections, and displacement of the contents of the abdominal cavity. The degree of dyspnœa in heart disease may be so slight that the patient himself may only observe it on over-exertion. Later, it is induced by less and less effort, until ultimately—when cardiac failure is severe—dyspnœa is brought on by such slight forms of exertion as walking at the ordinary rate on the level, or on changing position in bed; it may be present, indeed, without any effort of any kind. The degree of dyspnœa may amount to orthopnœa; that is, the patient may be unable to lie down.

A peculiar form of breathlessness which may occur in heart disease is what is often termed "cardiac asthma." This condition is characterized by paroxysms of breathlessness, the attack coming on suddenly, with a sense of suffocation—the intensity of which may be extreme—compelling the patient to sit up in bed, and to breathe in a very laboured fashion; wheezing sounds may be present, and the patient may cough up frothy sputum. After a time, it may be a few hours, the attack quickly subsides. These attacks are frequently nocturnal, and the patient is apt to suffer from what are called "night starts"—that is, he starts up with a sensation of suffocation; this is apt to occur when he is falling off to sleep. When a patient suffers from paroxysms of breathlessness, we should always be careful to exclude bronchial asthma, renal disease and hysterical dyspnœa. The syndrome known as

Cheyne-Stokes respiration may occur as a symptom in cardiac failure, and is usually of serious import; it should be distinguished from other forms of periodic respiration, such as are occasionally found in children during sleep, and also in meningitis. It may be present for days, or even for some weeks, and yet ultimately disappear.

While ordinary dyspnoea on exertion may occur in all forms of heart disease, it is more pronounced in mitral than in aortic disease; in mitral disease, indeed, it is usually the earliest symptom noted by the patient. Cardiac asthma and Cheyne-Stokes respiration are most apt to occur in chronic myocardial disease, especially with hypertension.

Palpitation may be a symptom of cardiac failure; but it should be remembered that it is more frequently met with apart from organic heart disease, especially in females. When due to cardiac failure, the palpitation is much more frequently referred to physical or mental exertion. A common symptom of cardiac failure is a sense of exhaustion during or after physical or mental effort.

Pain in the præcordium is a frequent symptom of cardiac failure, being of more common occurrence in aortic disease and in chronic myocardial disease than in mitral disease; but it should be remembered that pain is also met with apart from organic heart-disease, especially in females. When due to cardiac failure, the most characteristic feature of the pain is that it is brought on by physical or mental exertion—though it should be noted that it may not come on for some hours after the exertion which has induced it; and it is much more often constant, dull and aching than recurrent and sharp in character. The pain of angina pectoris, on the other hand, is usually over the sternum. Accompanying pain, or occurring independently of it, there may be a sense of constriction in the chest, and tenderness in the præcordium may also be associated with it.

Cerebral symptoms, the result of cerebral anæmia, due to failure on the part of the heart to maintain an adequate supply of blood to the brain, may depend upon a fault in the heart itself, occurring most commonly in aortic disease, chronic myocardial disease, and disordered cardiac action, such as paroxysmal tachycardia, 1:1 auricular flutter, or Adams-Stokes syndrome. Among these symptoms are giddiness, syncope or fainting attacks, attacks closely resembling *petit mal*, lack of power of concentration, early fatigue on mental effort, impairment of memory, sleeplessness, disagreeable dreams, nervousness, loss of emotional control, mental irritability, and, in severe cases, delirium, hallucinations, or even insanity. Giddiness may be slight and transient, or severe enough to cause the patient to fall. Syncope or fainting attacks are usually preceded by a preliminary sensation of great weakness, giddiness, loss of sight, and, it may be, nausea and vomiting; while during the attack the face becomes of a greenish pallor, the patient breaks out into a clammy sweat, respiration almost or completely ceases, and the pulse at the wrist becomes very feeble or even imperceptible; the return to consciousness is gradual. It is important to note that giddiness and faintness may not depend upon a fault in the heart itself, but upon a fall in blood-pressure, due to vaso-motor derangement, in which the venous return to the heart fails; in which connexion it is of fundamental diagnostic importance whether they are more associated with physical exertion or changes of posture. Attacks closely resembling *petit mal* may occur in elderly people, especially

in those with arterial disease and chronic myocardial disease, and it is sometimes extremely difficult to distinguish them from fainting attacks. The distinguishing features of the latter have already been described. Adams-Stokes syndrome may occur. This is described on page 866.

5) Edema is an important manifestation of cardiac failure, and is more liable to occur in mitral than in aortic lesions. It usually commences in the most dependent parts, and generally the patient first notices some puffiness round the ankles in the evening. Even in severe and prolonged cases, the oedema is often confined to the lower extremities; but, occasionally, especially in children, it is first observed in the face, and, when this is the case, renal disease is often suspected. Towards the final stages it may become general, even when the kidneys are unaffected. Edema may involve the serous membranes, with resultant ascites, hydro-thorax, and occasionally hydro-pericardium. In mitral stenosis, it is not very infrequently limited to the peritoneal cavity. The urine may be scanty, high-coloured, exhibit an excess of urates, and may contain albumin, or even blood.

6) Affections of the respiratory system, such as bronchitis and broncho-pneumonia, are liable to occur in heart disease, especially in mitral affections. Hæmoptysis is not uncommon; mitral disease, indeed—especially stenosis, is one of the commonest causes of blood-spitting, and the heart should invariably be examined when a patient presents himself with a history of hæmoptysis. Hæmoptysis occurring in chronic valvular disease may be the result of chronic venous congestion or pulmonary infarction. There may be chronic venous congestion and oedema of the lungs, particularly of the bases, and, later, hypostatic pneumonia. More rarely, pulmonary infarction may be present. The existence of pleural effusion should always be borne in mind in cases of dyspnœa; when present, it is generally bilateral. Acute pulmonary oedema is rarely met with; in these cases intense dyspnœa comes on suddenly, and is accompanied by the appearance of frothy mucus which wells out of the mouth and nose in quantities, the patient usually dying within a few hours of the beginning of the attack.

Loss of flesh may be present in cardiac failure, and, when heart disease occurs in the early years of life, development may be arrested. Digestive disturbances are not uncommon in, and may give early indications of, cardiac failure, being due either to deficient blood supply or chronic venous congestion of the alimentary organs, usually the latter. These may take the form of loss of appetite, a sense of fullness and oppression after meals, pain in the epigastrium and between the shoulder-blades, nausea, vomiting, gastric and intestinal flatulence, and constipation or diarrhœa. Hæmatemesis and melæna are of rare occurrence, and, if severe, are usually due to associated hepatic disease. When tricuspid regurgitation and venous engorgement have become established, the liver may be palpable, having a sharp edge and smooth surface, and may be tender and rarely pulsates. Later, jaundice and ascites may develop. The spleen may be increased in size, though it is generally smaller than normal, unless there is infarction or chronic septicæmia. There may be menorrhagia or metrorrhagia, due to congestion of the uterine mucous membrane.

In heart disease, especially in affections of the mitral valve, there is often a persistent dusky flush over the cheeks, while later there may be lividity of the lips, ear-tips and cheeks, and clubbing of the finger-tips may be present

in chronic cases. In aortic disease, on the other hand, the face is generally pallid and anxious, though in some cases the colour may be high; while, later, when relative incompetence of the mitral valve has become established, the facies resembles that which is characteristic of mitral cases. An icteric tinge of the skin may also be present.

Embolism, as well as arterial and venous thrombosis, may be an expression of cardiac failure.

With regard to the pulse, while increased frequency is the rule, bradycardia is occasionally to be noted in cardiac failure. The volume and force of the pulse may become diminished. The arterial pressure varies, and is, therefore, not a reliable indication of cardiac failure; it may be subnormal, but, on the other hand, it may be even supernormal until shortly before death. The apex-beat is usually displaced outwards, may be diffuse, and difficult or even impossible to locate. On percussion, the area of cardiac impairment is generally increased transversely to the right or the left, or both. On auscultation, modifications in the cardiac sounds and the cardiac cycle, as described elsewhere, may be present. Distension and pulsation of the jugular veins and other indications of tricuspid incompetence (to be described later) may be present.

Lastly, sudden death may occur, even without previous indications of cardiac failure.

The indications of failure of the left ventricle are chiefly those of systemic anæmia, the indications of failure of the left auricle are pulmonary in character, while the indications of failure of the right side of the heart are those of systemic venous congestion. It should be noted that there may at the same time be indications of failure of all the chambers of the heart, with those of one chamber predominating. The symptoms of cardiac failure in mitral disease are principally pulmonary and, later, those of systemic venous congestion. The symptoms of cardiac failure in aortic disease, on the other hand, are at first usually mainly those of systemic anæmia, or angina pectoris; later on, however, *relative* mitral incompetence is apt to occur, with consequent pulmonary symptoms and, later, symptoms of systemic venous congestion. It should be noted that dyspnoea on exertion is perhaps the most frequent symptom of aortic disease, and may be the result of systemic anæmia and also pulmonary in origin. Præcordial pain is of more common occurrence in aortic than in mitral disease; while gastro-intestinal symptoms, dropsy, and embolism are of less frequency.

The type of heart failure associated with chronic venous congestion is often described as *congestive heart failure*.

It may be helpful to indicate what, in my opinion, speaking broadly, may be regarded as clinical manifestations of four degrees of cardiac failure—namely, “slight,” “moderate,” “severe,” and “extreme.” *Slight*: Shortness of breath, palpitation, fatigue and, it may be, præcordial pain on exertion, which the patient formerly could do without experiencing this. *Moderate*: Shortness of breath and palpitation on moderate exertion, such as walking quickly on the level; slight cedema of the lower extremities; slight enlargement of the liver; chronic venous congestion and cedema of the bases of the lungs; some degree of increased rapidity of the pulse while at rest. *Severe*: Shortness of breath and palpitation on slight exertion, such as walking at the ordinary rate on the level, or on changing position in bed;

a considerable degree of œdema of the lower extremities in mitral cases and moderate degree in uncomplicated aortic cases; a considerable degree of enlargement of the liver; orthopnoea; cardiac asthma; diffuse chronic venous congestion and œdema of the lungs; slight acute pulmonary œdema; œdema of the serous membranes; tic-tac rhythm; gallop rhythm. *Extreme*: Continuous shortness of breath; severe dyspnoea on walking slowly on the level, or on changing position in bed; general anasarca in mitral cases and a considerable amount of œdema of the lower extremities in uncomplicated aortic cases; marked enlargement of the liver; severe acute pulmonary œdema; pulsus alternans in the absence of a severe grade of tachycardia.

The degree of cyanosis *per se* is not a reliable indication of the degree of cardiac failure, since it largely depends upon the variety of the cardiac affection.

PROGNOSIS IN CARDIAC AFFECTIONS

Prognosis in cardiac affections is a subject of the utmost importance, and often presents great difficulties. From the nature of the ailment, the reasons for the importance of prognosis are not far to seek. Among these are the fact that the patient and his friends are naturally anxious for, and have the right to, an opinion, based upon a full consideration of all the circumstances of the case, as to the probable duration of life, the ability of the patient to lead within limits a fairly normal existence, and perhaps also his capacity for employment. This is a very natural anxiety, which if unrelieved may have a most injurious effect upon the general health and well-being of the patient. It is a misfortune that in the popular view there is a tendency to group together all classes of cardiac affections as necessarily of serious import, the result being that in a considerable proportion of cases quite needless anxiety may be occasioned.

In trying to form a prognosis in any given case of cardiac disorder, the following points, among others, require consideration: the family history, the age, the sex, the occupation, the mode of life and the social conditions of the patient; the age-incidence of the cardiac affection; the health of the patient subsequent to the commencement of the cardiac affection; the cardiac affection—its ætiology, its variety, its degree, its duration, and whether it is stationary or progressive; the integrity of the myocardium; the question of cardiac failure; the risk of sudden death; the general health of the patient, and the existence or otherwise of complications; and the response of the patient to treatment.

With regard to the family history, we should particularly note whether any other members of the family have suffered from any form of cardiovascular disease, and the average period of longevity. The question of age is one of considerable importance. The younger the patient the more likely is the cardiac affection to be the result of antecedent acute inflammation, as, for example, chronic valvular disease, or chronic interstitial myocarditis, the result of a previous attack of acute endocarditis, or acute myocarditis respectively. At or after middle life, on the other hand, the cardiac affection is more likely to be due to a primary chronic affection, as, for example, chronic valvular disease the result of primary chronic endocarditis, or chronic interstitial myocarditis which is primary. In the case of cardiac affections

due either to antecedent acute inflammation or to a primary chronic affection, after adult age, the cardiac reserve is more likely to be less as age advances. Taking all cases of cardiac affections into account, the prognosis is better in females than in males. Among other reasons for this is the fact that the former are less subject to physical and mental strain, in them mitral disease is relatively more common than aortic disease, and chronic myocardial disease and arterial disease are relatively of less frequent occurrence. On the other hand, mitral stenosis is much more common, and the strain at puberty is greater in females than in males, and, further, the risks of pregnancy and parturition have to be considered. Any occupation or mode of life involving undue physical or mental strain or exposure, and unhealthy habits, such as over-eating or over-drinking, render the prognosis less favourable. The prognosis is considerably modified for the worse also if the patient be unable, when this is found to be necessary, to change an unfavourable occupation for one more suitable; or if he be compelled to live under unsatisfactory hygienic conditions as to food, fresh air, and the opportunity for rest so necessary in those suffering from cardiac affections; or, if after suitable treatment has been instituted, a return has to be made to an unfavourable environment.

The younger the age-incidence, the less favourable the prognosis. Among the reasons for this are that : (1) in early life the heart is less able to undergo compensatory changes during the period of active growth, and any form of cardiac affection has a deleterious effect upon the general physique and mental development; (2) in early life rheumatic endocarditis is more likely to be accompanied by myocarditis and pericarditis; and (3) there is a greater liability to the recurrence of the cause of the cardiac affection, with possible increased damage to the heart. If the cardiac affection has existed for a considerable time, and the health of the patient is still good, the outlook is correspondingly hopeful; and the converse is the case.

Taking cases as a whole, when the cardiac affection is due to a previous attack of acute endocarditis, the prognosis is not so serious as when due to a primary chronic affection; because in the latter case the lesion is apt to come on after middle life, to be progressive, and to be associated with chronic myocardial disease. It should, however, not be forgotten that when the affection is due to a previous attack of acute endocarditis, the patient is liable to recurrent attacks and consequent further crippling of the valve. If the lesion is due to syphilis, taking cases as a whole, the prognosis is very unfavourable.

With regard to the variety of the cardiac affection, the prognosis of aortic is less favourable than that of mitral disease, and lesions affecting both valves graver than when one only is involved. It is a matter of no small difficulty to give the order of relative gravity of lesions affecting the different valves, but so far as four varieties of chronic valvular disease are concerned, some authorities place in order of gravity, aortic incompetence, mitral stenosis, aortic stenosis, and mitral regurgitation. With regard to aortic stenosis, however, a qualification is necessary; it refers only to those cases which are due to antecedent acute endocarditis. Among the points which may be of assistance in trying to estimate the degree of the cardiac affection are the degree of modification of the character of the pulse, of the blood-pressure, of the cardiac sounds and cycle, the size of the heart, the time

of occurrence, the duration, the character, and the area of propagation of any existing murmur or murmurs, and the degree of any existing auriculo-ventricular block. As examples, in chronic valvular disease: in mitral and tricuspid stenosis, the duration of a presystolic murmur and whether there is also a diastolic murmur, and if so, its length; and in mitral incompetence and aortic incompetence, whether a murmur merely accompanies or replaces the cardiac sound, its length, and its area of propagation. When the cardiac affection is the result of a previous attack of an acute inflammation, as, for example, chronic valvular disease due to a previous attack of acute endocarditis, generally speaking, the shorter the duration the less favourable the prognosis. Among the causes for this are: (1) there is less chance that the inflammatory process has become quiescent; (2) it is less possible, especially in mitral stenosis, to estimate whether the fibrous cicatricial tissue resulting from the acute inflammatory process has ceased to contract; and (3) the patient is more liable to recurrent attacks of the cause, such as acute rheumatism, with possible consequent further damage. In endeavouring to arrive at a decision whether the cardiac affection is stationary or progressive, the following points should be considered: whether the standard of the response of the heart to effort is lower; the question of cardiac failure; whether there is an increase in the degree of modification of the character of the pulse, of the blood-pressure, and of the cardiac sounds and cycle; the size of the heart; whether there is an alteration in any existing murmur or murmurs—such as whether a murmur replaces instead of accompanies the cardiac sound, or an increase in the length of an apical presystolic, or the supervention and the length of an apical diastolic murmur; and is there an increase in any existing auriculo-ventricular block?

The integrity of the myocardium is of the utmost importance in all cases. Is it involved or not, and if so, to what degree? In this connexion the response of the heart to effort and the question of cardiac failure are of great value, and are dealt with elsewhere. In addition, the size of the heart, to what extent the cardiac sounds and cycle are modified, the cardiac rhythm, including whether there is auriculo-ventricular block, and, if so, of what degree, whether there is bundle-branch block, intraventricular block, or some other form of disordered action of the heart, are important. When the degree of limitation of the response of the heart to effort, and, if present, the degree of cardiac failure are in excess of what might be expected considering the variety and degree of the cardiac affection, provided a cause for such can be excluded, the greater likelihood, and the more severe the degree, of myocardial involvement.

The question of cardiac failure is of very great importance. In all cases in which cardiac failure is present, two points should invariably be taken into consideration, namely, its degree and the circumstances of its onset. The clinical manifestations of the various degrees of cardiac failure are described on pp. 828-829. With regard to the second point, inquiry should be made as to whether the cardiac failure is, or is not, due to a cause which might reasonably be expected to account for it, and is either temporary and not likely to recur, or persistent but remediable.

With reference to the risk of sudden death in cardiac affections, the commonest cause of such is atheroma of the coronary arteries. Such an event may be due to coronary occlusion, or independent of it. Sudden

death is not uncommon in cases of angina pectoris, and may be due to ventricular fibrillation, coronary occlusion, or possibly apart from these. The liability to sudden death is greater in myocardial than in valvular disease. Rupture of the heart, the result of cardiac infarction, is a rare cause. In such cases death may occur during the first week after coronary occlusion, or later as the result of aneurysm of the ventricle. Of the valvular diseases sudden death is most frequent in aortic incompetence. This may be due to the occurrence of ventricular fibrillation. In valvular disease sudden death may result from a large pulmonary embolism. Other causes of sudden death are Adams-Stokes syndrome, and rupture of the aorta in syphilitic aortitis or dissecting aneurysm.

The prognosis is also influenced by the state of the patient's general health and the existence or otherwise of complications, among the latter being arterial disease, hypertension, renal disease, chronic bronchitis, and emphysema.

Finally, the prognosis in cardiac affections must be considered in the light of response to treatment. For example, given a case of auricular fibrillation with a rapid ventricular rate, with indications of severe cardiac failure, it is impossible to say what the future will be until full doses of digitalis have been administered.

Having now reviewed the various points which may arise in the consideration of the prognosis of most cardiac affections, these need not be again referred to when the prognosis of individual cardiac affections comes under discussion.

TREATMENT IN CARDIAC AFFECTIONS

IMPORTANCE OF TREATMENT IN CARDIAC AFFECTIONS.—In few departments of medicine is careful and skilful treatment of so great importance as in that of cardiac disorders, and in few is it so well rewarded. For although we cannot rectify the actual lesion in the case of a damaged valve or myocardium, it is none the less true that in a large proportion of cases it is possible by the adoption of proper and adequate therapeutic measures to prolong life for many years, and in most cases to save patients from much suffering. Moreover, the work which has been done in recent years in the realm of cardiac disorders has resulted in a great advance with regard to what can be accomplished in the large class of patients who are the subjects of auricular fibrillation, or of auricular flutter. At the outset, therefore, I would emphasise the fact that the practitioner will be amply rewarded for any time spent and patience exercised in considering and putting into practice suitable therapeutic measures for any given case of heart disease which may come under his care.

It is desirable to devote one section to the consideration of the therapeutic measures which may be applicable to any form of cardiac disorder, in order to save much needless repetition when we come to consider the treatment of the individual cardiac affections.

OBJECTS OF TREATMENT.—The primary object is to prevent the super-vention of cardiac failure, or complications, and, if present, to adopt prompt and suitable treatment. With regard to the question of cardiac failure, if the view that its essential cause lies in the heart muscle be accepted, then on

the one hand the patient should avoid anything which puts a strain upon the myocardium, and, on the other hand, the practitioner should do everything in his power to promote its efficiency. In addition to the foregoing, cardiac failure, symptoms and complications should be treated as they arise.

INSTRUCTIONS REGARDING MODE OF LIFE.—Given a cardiac affection, it is most unfortunate that such a large proportion of patients endeavour, or are compelled, to live beyond the limits of the heart's strength; a constant strain is thus thrown upon the organ. It is, therefore, of the utmost importance that the patient should endeavour to live within the limits of his diminished cardiac strength. Nevertheless, he should have an adequate amount of exercise, and, moreover, care should be taken not to restrict unnecessarily his usual mode of life, since otherwise he is apt to become nervous and introspective. With regard to the amount of physical exertion which the patient may undertake without harmful effects, it is impossible to lay down hard-and-fast rules. It is possible, however, to enunciate a cardinal principle which will be found of inestimable service in these cases, namely, that any exertion which the patient may undergo should not be attended or followed by breathlessness, palpitation, fatigue, a sense of tightness or oppression, or discomfort or pain in any part of the front of the chest, or giddiness, or faintness. On the other hand, any exertion short of producing these symptoms is usually not harmful providing violent and sudden effort be avoided, and a sufficient amount of exercise is in every way desirable. It is not enough to regulate the amount of physical exertion only; the importance of attending to the amount of mental work in these cases is not sufficiently appreciated. When the cardiac affection is progressive, the amount of effort, physical and mental, should be correspondingly reduced.

All excitement, worry, and other forms of emotional strain should be avoided. If the patient suffers from an unduly excitable nervous system, or is prone to worry or to be anxious, the bromides are often exceedingly useful. The ammonium salt is less depressant than the potassium salt, and in such cases 40 grains per diem should be prescribed, gradually diminishing this amount to a single dose of 10 grains each or every other day, which may be continued, if found to be helpful, and a larger dose may be resorted to if and as required. Failing bromides, bromide and valerian, adalin, allonal, or luminal, may be tried. It is difficult to over-estimate the importance of sleep, and inquiry should invariably be made regarding its amount and character, and if any defect be found, it should be treated on the lines laid down later on.

In most cases the daily amount of fluid taken should be somewhat restricted, our aim being to lessen the amount of work done by the left ventricle by diminishing its output. The meals should be as dry as the patient will take them, a sufficient amount of fluid being taken between meals. The three meals of the day should be evenly balanced, since a large meal at one time causes too great a variation in the vascular system, to which the heart does not readily adjust itself. The food should be nutritious, easily assimilable, and not likely to cause indigestion. A diet of carbohydrates is bulky, and is apt to cause flatulence and hyperchlorhydria, while a diet consisting of highly nitrogenous food increases the resistance in the peripheral circulation and is equally to be avoided. While, therefore, the diet should be a carefully mixed one, the albuminous element should predominate. Any article of

diet which causes flatulent distension of the stomach or bowels should be avoided, since this, by direct pressure, embarrasses the heart and is one of the commonest causes of palpitation. In the opinion of most, a salt-free diet is of value as an aid in preventing senile changes in the arteries, and in the treatment of hypertension and atheroma. The excessive use of tea, coffee and tobacco should be avoided. It is better for the patient to abstain from alcohol altogether; but if he has been accustomed to its use and deprivation be a great hardship, a strictly moderate amount of well-diluted spirit, or light wine, taken with meals, may be allowed. Strict attention to the condition of the bowels is indicated.

Any existing anæmia in patients suffering from heart disease should be effectively treated. Those who exhibit any gouty tendency should also be attended to. Periodic courses of such tonics as iron, arsenic, phosphorus, strychnine, or quinine may be taken with advantage from time to time; while in children, cod-liver oil, the syrup of phosphate of iron, or the syrup of iodide of iron is of especial advantage.

The question of focal sepsis, especially in the teeth, the tonsils, the accessory nasal sinuses, the pharynx, the colon, the appendix, chronic cholecystitis, and the genito-urinary tract, is an important one and should receive attention. In cardio-vascular disease, especially when of mitral origin, it is important to guard against influenza. Any attack of influenza or bronchitis should be promptly treated, and on no account should convalescence be hurried.

REST.—Rest is of cardinal importance in the treatment of cardiac failure. It is, indeed, difficult to exaggerate its value. It is not sufficiently appreciated that cardiac rest is the objective of all therapeutic measures. Details regarding its application are dealt with elsewhere.

SYSTEMATIC EXERCISES.—Systematic and graduated exercises are sometimes useful in cardiac affections, provided they are judiciously employed and their effect watched. They are of special help in cases of slight cardiac failure due to the heart muscle being flabby and lacking in tone, as in fatty infiltration. Contra-indications for their use are acute affections of the heart, a severe degree of chronic valvular disease or of chronic myocardial disease, "severe" cardiac failure, and cases in which the heart failure is progressive. Simple movements, especially of the Swedish variety, are, in most cases, better than resistance exercises. Systematic exercises may be indulged in even when the patient is confined to bed. In all cases, they should stop short of inducing any indications of cardiac distress or *maintained* increased frequency of the ventricular rate; and they should be followed by a period of absolute rest.

MASSAGE.—Massage is more often useful than is generally appreciated. The same considerations apply as in the case of systematic exercises. Massage may also be employed when the patient is confined to bed, in cases in which absolute rest is not necessary, but in which on the other hand ordinary muscular exercise is not advisable.

BATHS AND SPA TREATMENT.—It is commonly known that immersion of the body in water may exercise a decided influence on the circulation. It is, further, believed by some that certain waters at Nauheim, on account of their ingredients, possess a specific therapeutic value in cardiac affections, but I am very sceptical with regard to this. Patients undoubtedly often derive

very great benefit from a stay at Nauheim and at similar spas; but this appears to be due to the rest, the change of air, the regular mode of life and exercise, the careful dieting, and other factors. Given the same conditions of life, equally good results would be obtainable elsewhere. Spa treatment is particularly serviceable in patients who have indulged in excesses of various kinds.

THE DIGITALIS GROUP OF DRUGS.—This includes, among others, digitalis, strophanthus, squills, convallaria majalis, and apocynum. All these drugs have a similar action on the heart, but as digitalis is by far the most reliable, the only other drug which need be considered is strophanthus, which is used for intravenous administration.

Preparations.—The official preparations of digitalis and strophanthus contained in the British Pharmacopœia, 1932, are standardised by biological assay in terms of international units. Powdered digitalis leaf (*Digitalis pulverata*, B.P., 1932, dose, $\frac{1}{2}$ to $1\frac{1}{2}$ grains; single doses, 3 to 10 grains); tincture of digitalis (B.P., 1932, dose, 5 to 15 minims; single doses, 30 to 90 minims); tincture of strophanthus (B.P., 1932, dose, 2 to 5 minims); and strophanthin (B.P., 1932, dose, $\frac{1}{10}$ th to $\frac{1}{6}$ th grain) are standardised. One grain of the powdered digitalis leaf corresponds approximately to ten minims of the tincture. It is generally administered in the form of tablets, which are claimed to be particularly stable. Tincture of digitalis and tincture of strophanthus undergo decomposition when freely diluted with water, and for this reason should be dispensed either undiluted or diluted with alcohol or brandy. Strophanthin is extremely irritant, and therefore should on no account be administered subcutaneously or intramuscularly.

Digitalis (or strophanthus) is indicated in auricular fibrillation with ventricular tachycardia, in auricular flutter (see p. 880), in either case whether congestive heart failure is present or not; and in congestive heart failure, especially if the amount of urine is diminished or dropsy is present; in all cases whatever the cardiac lesion may be. The drug is likely to prove far more effective when cardiac failure is associated with auricular fibrillation with a rapid ventricular rate, or auricular flutter with a rapid ventricular rate, than in cases with a rapid ventricular rate associated with normal rhythm. In the former cases, the results of the administration of the drug in the majority of cases are very, and in some cases extraordinarily good; it is followed by a rapid fall in the ventricular rate (Fig. 26) and a concomitant improvement in the general symptoms. When auricular fibrillation or

FIG. 26.—Chart showing typical result on the cardiac rate of the administration of digitalis in a case of auricular fibrillation with tachycardia. A drachm of the tincture per diem was commenced on 27th January.

auricular flutter is not accompanied by a rapid ventricular rate, no marked result usually follows the administration of the drug.

Digitalis is more generally useful in mitral than in aortic cases; in all probability the explanation of this is that both auricular fibrillation and congestive heart failure are much more common in mitral lesions. The question is often asked whether digitalis should be given in cases of aortic incompetence, and formerly there was a difference of opinion on this point, but there is now general agreement that when the indications already mentioned are present in such cases, the drug is indicated. I am not convinced that there is any special danger from digitalis in this variety of valvular disease. Hypertension and arterial disease are not contra-indications for digitalis, as my own investigations have shown, and the drug should be employed in the ordinary way if the indications noted are present. Digitalis is often beneficial in such cases when there is cardiac asthma. Some authorities advocate vaso-dilators combined with digitalis in hypertension, but I have not been favourably impressed by their use. In cases in which there is accompanying pyrexia, and also in thyro-toxic conditions, there may be little response to digitalis, even when auricular fibrillation with a rapid ventricular rate, or auricular flutter with a rapid ventricular rate is present. Digitalis is contra-indicated in persistent heart-block. Moreover, caution should be exercised and large doses avoided in acute lesions of the myocardium, such as rheumatic carditis, or cardiac infarction.

In the great majority of cases the aim of digitalis medication is to accumulate in the body a sufficient quantity of the drug to produce a full therapeutic effect; and in the majority of these afterwards to maintain that quantity there. In order to attain the first object, the intake of the drug should be greater than the amount excreted until full digitalisation has been produced; and for the second purpose, the dosage should be reduced to such an extent as will balance the excretion, with consequent maintenance of digitalisation.

In a certain proportion of cases, however, it is not necessary to proceed to full digitalisation, a modern dosage for a period being sufficient; and in the majority of these improvement can be afterwards maintained without continuing the drug.

If the first method is adopted, with regard to the dosage to commence with, the larger it is the more rapidly is full digitalisation produced. The choice of such in any individual case will depend upon the urgency of the patient's condition. For average cases, without urgent symptoms, a good method is to begin with 6 grains of digitalis leaf, or 1 drachm of the tincture, per diem, divided into three doses. In urgent cases, even 9 or 12 grains of the leaf, or its equivalent of the tincture, per diem is indicated.

In still more urgent cases, with a rapid ventricular rate, the method of massive dosage, first introduced by Eggleston in 1915, may be employed. In this method the total amount of digitalis required may be estimated from the patient's body-weight. There are various methods of doing this. One is that for every 10 lb. of body-weight approximately 0.1 gramme ($1\frac{1}{2}$ grains) of leaf, or 1 c.c. of tincture, is required. For example, a patient weighing 10 stone will require 1.4 grammes (21 grains) of leaf, or 14 c.c. of tincture. Half the quantity may be given as an initial dose and, unless toxic symptoms supervene, afterwards one or two quarter doses, in each case at intervals of

6 hours. More recently, a single massive dose has been advocated. The simpler method is to ignore the body-weight, and to give an initial dose of 9 grains, or $1\frac{1}{2}$ drachms, and, unless toxic symptoms supervene, afterwards one or two doses of 6 grains and 3 grains, or 1 drachm and $\frac{1}{2}$ drachm, respectively, at intervals of 6 hours. A single massive dose of digitalis will produce the full digitalisation effect in 4 to 6 hours, and divided doses in about 24 hours. No more of the drug should be administered for at least 24 hours. This method of treatment should only be used in the case of patients who are in bed and under constant observation. Moreover, this method of treatment is contra-indicated if digitalis has already been given by the mouth, unless the approximate total amount is known and does not exceed that which is moderate, and the massive dosage of digitalis should be diminished, and proportionately so according to the total amount of digitalis which has already been administered.

The intravenous injection of strophanthin may be employed in still more urgent cases, or when there is vomiting. The dose may be up to $\frac{1}{80}$ th grain. A massive dose, $\frac{1}{80}$ th to $\frac{1}{33}$ rd grain, has been advocated recently, but as yet I would not advise this. The drug should not be repeated within 24 hours, depending on the patient's condition, and, if so, in a smaller dose. This method of treatment is contra-indicated if digitalis has already been given by the mouth, unless the approximate total amount is known and does not exceed that which is moderate, and the dose of the strophanthin should be diminished, and proportionately so according to the total amount of digitalis which has already been administered. Moreover, strophanthin is a powerful poison in overdosage, and the best therapeutic dose is very near the toxic dose. It follows, therefore, that whether the drug should be used or not and, if so, its precise dose, require the most careful consideration, and the drug should be injected very slowly. Digitalin, $\frac{1}{100}$ th gr., may also be given intravenously.

Digitalis can be absorbed from the rectum, and this method of administration may be employed when there is vomiting. The dosage is the same as that by the mouth. A simple enema is given a few hours previously in order to prepare the bowel for absorption, and the tincture of digitalis should be diluted with warm saline to a bulk of 3 oz., and introduced slowly through a funnel. A single massive dose of 1 c.c. of tincture per 10 lb. body-weight may be employed, or the total quantity may be subdivided in the manner already described.

If full digitalisation has been obtained, in the majority of cases the indication then is to find out the optimum maintenance dosage, *i.e.* the dosage sufficient to control the action of the heart, without at the same time giving rise to any toxic symptoms. This may require even months of careful observation. In this connection, the patient's own sensations are often helpful, and should be taken into consideration, as well as the ventricular rate. The optimum maintenance dosage may exhibit a wide variation in different patients, but is usually 1 to 3 grains of the leaf, or 10 to 30 minims of the tincture, per diem. In the course of time, variation in the dosage may be found to become necessary. The accumulative action of the drug is apparently not nearly so important as was formerly believed. At the same time, the patient should be watched for overdosage.

Among the indications of overdosage of digitalis are anorexia, nausea,

vomiting, headache and diarrhoea. It should be observed that vomiting is not uncommon in cardiac failure apart from the administration of digitalis, and therefore vomiting is not necessarily of toxic origin. The effect on the heart may be to produce occasional ventricular extra-systoles, *pulsus bigeminus* or *coupling of the beats* (Fig. 43). More serious indications are runs of extra-systoles, multifocal extra-systoles, and even ventricular tachycardia. Undue slowing of the pulse may also occur. In auricular fibrillation this is the result of diminished conductivity of the auriculo-ventricular junctional tissues. In normal rhythm it is due to the depressive action of the drug upon the sinus, and ventricular escape may occur. The occurrence of toxic symptoms is an indication to stop digitalis altogether for at least 24 hours, after which the dosage should be diminished.

Digitalis has no effect upon the auricular fibrillation itself; but it diminishes conductivity of the auriculo-ventricular junctional tissues, thereby interfering with the pathway of impulses from auricle to ventricle, and so cutting off some of the too numerous impulses reaching the ventricle, and thus leading to a reduction of the ventricular rate, as a result of which the cardiac contraction becomes stronger, with consequent improvement in the circulation and in the general symptoms.

In auricular flutter, the administration of full doses of digitalis at first usually induces partial heart-block, or an increase in the degree of block already existing, with a resulting diminution of the ventricular rate. Later on, the drug may induce auricular fibrillation. The change to auricular fibrillation is usually an advantage, because the ventricular rate can generally be more easily controlled by moderate doses of digitalis than in the case of auricular flutter. Auricular fibrillation may persist, or the physiological rhythm may be restored—either event occurring during the administration of the drug or after it has been discontinued. After the restoration of normal rhythm, recurrences of flutter are not uncommon. The same considerations regarding the dosage and method of administration of digitalis (or strophanthus) apply in auricular flutter as in auricular fibrillation with a rapid ventricular rate. For further details, see p. 880.

Quinidine.—Quinidine is employed in the treatment of persistent auricular fibrillation and persistent auricular flutter, more especially the former, with the object of arresting either condition—in other words, to restore the normal rhythm. It is also used in paroxysmal tachycardia, including that due to paroxysmal flutter or paroxysmal fibrillation, in the intervals between the attacks, to prevent their recurrence. In persistent auricular fibrillation, the normal rhythm can be restored in about half of the cases, but as relapse is relatively frequent the drug is less often used than formerly.

Quinidine is a cardiac depressant, and it acts directly on the auricular muscle and by depressing the vagus. It prolongs the refractory period of auricular muscle and slows the conduction rate. Prolongation of the refractory period tends to interrupt the circus movement in the auricles (see p. 873), while slowing of conduction favours its continuance. Where the action on the refractory period predominates, the circus movement is abruptly terminated and the normal rhythm is restored. The slowing of the rate of the circulating wave in the auricles tends to increase the frequency of the ventricular response, so that the ventricular rate rises during quinidine administration, before normal rhythm returns. This tachycardia may be prevented

to a large extent by giving a preliminary course of digitalis before commencing quinidine. Extra-systoles may be observed after the auricular fibrillation has ceased, and may give rise to palpitation. They occur as a general rule only when the auricular rate has diminished considerably, generally to 250–300 per minute. Their appearance is an indication of poisoning.

In persistent auricular flutter, the administration of quinidine may restore the normal rhythm. It is, however, less successful than in persistent auricular fibrillation.

General toxic symptoms, cardiac failure, and embolism may occur during the administration of quinidine. Among general toxic symptoms are headache, giddiness, tinnitus, transitory visual disturbance, nausea, vomiting, abdominal pains, palpitation, præcordial pain, sweating, scarlatiniform or morbilliform rashes, urticaria, a mild degree of pyrexia, fainting attacks, and mental symptoms. Among the manifestations of cardiac failure are sudden collapse, sudden cessation of respiration, severe dyspnoea, cyanosis, and disappearance of the pulse—due to ventricular standstill during the transition stages. The risk of embolism occurs at the time when the auricle first commences to contract again after the restoration of the normal rhythm. Thrombi are expelled from the auricular cavity into the systemic or pulmonary circulation, and death may result. Death during the administration of the drug may be due to cardiac failure or to embolism.

In persistent auricular fibrillation or persistent auricular flutter quinidine is most likely to be successful in those cases in which there is at the most only a moderate degree of valvular or myocardial disease, of cardiac enlargement, and of cardiac failure; in those in which the abnormal rhythm is the result of antecedent rheumatism or chorea; in cases in which there is an absence of acute endocarditis, or acute myocarditis; when the onset of the condition has occurred during an acute infection—such as influenza; when the abnormal rhythm has followed paroxysmal attacks, and, in the opinion of some, when of recent origin; and in the case of the young. The majority of successful cases follow the use of only small doses of the drug, and it is rarely successful if more than 30 grains per diem are required. Relapse into the abnormal rhythm occurs, in the majority of cases, sooner or later, after the drug has been stopped.

Among the disadvantages of quinidine is the risk attending the administration of the drug, the fact that restoration of the normal rhythm occurs in only about half the cases of auricular fibrillation, that there is a danger of relapse into the abnormal rhythm, and that in some cases after the restoration of the normal rhythm the general health is worse. Contra-indications for the use of the drug are the presence of a severe grade of valvular disease, severe myocardial disease, great enlargement of the heart, a severe degree of cardiac failure—unless this has been remedied by a course of rest and other therapeutic measures, heart-block, existing or recent acute or sub-acute endocarditis or myocarditis, a recent history of embolism, and in those cases when the patient cannot be confined to bed and be assiduously and carefully watched.

A preliminary course of rest in bed and of digitalis medication is advisable. It is the practice of some to stop the digitalis for a few days before commencing quinidine, while others continue its use during the administration of the latter, in order to control the ventricular tachycardia. The patient

should invariably be confined to bed, absolute rest, physical and mental, should be enjoined, and he should be assiduously watched. Frequent electrocardiographic examinations are very advisable. Quinidine is given preferably in gelatine capsule form. It is advisable to give a single dose of 5 grains, or two doses of 3 grains at an interval of 2 hours, to test for possible idiosyncrasy, and if none is found to exist, to commence the routine treatment the following day. Five grains three times daily may be commenced with, and the total daily dosage gradually increased up to 30 grains, which may be continued until normal rhythm is restored, or until symptoms of intolerance appear. The dosage of 30 grains per diem is usually safe, and should rarely be exceeded, though far larger doses have been used. The drug should be stopped if severe toxic symptoms, severe cardiac failure, or embolism, occur, or if there is an auricular rate of 250 or 240 per minute—because of the risk of inducing 1 : 1 rhythm, or, as a rule, if there is a ventricular rate above 160. After the normal rhythm has been restored, the total daily dosage should be gradually diminished to 5 grains twice, or even once, daily, and this continued for an indefinite time or even permanently. This method lessens the likelihood of relapse.

When quinidine is employed in paroxysmal tachycardia, in the intervals between the attacks to prevent their recurrence, the dosage is 5–15 grains per diem.

Investigations which I conducted some years ago showed that *aconite* has no effect upon the pulse-rate.

Caffeine has acquired a certain reputation in the treatment of cardiac affections, but this is, in the main, the result of its diuretic action, which is of great value. It should not, however, be regarded as a substitute for *digitalis*, for the action of the respective drugs on the heart is not the same. Apart from its diuretic action, caffeine may be tried when *digitalis*, *strophanthus*, and squills have failed, particularly where there is no dilatation. It does not slow the pulse, and therefore, bradycardia is no contra-indication to its use.

Diuretin, *agurin*, and *theocin-sodium-acetate* have a more constant and marked effect upon the kidneys than caffeine. They may be used in conjunction with one of the *digitalis* group.

Strychnine may be employed as a stimulant in cases of circulatory failure and syncope, but it has no direct action on the heart in heart failure. It should be administered in large doses, e.g. $\frac{3}{10}$ – $\frac{1}{10}$ th grain, in order to have an effect.

Diffusible stimulants (alcohol, ammonia and ether) are of value in some cases of cardiac affections, particularly during temporary attacks of cardiac failure, febrile cases, and for the relief of urgent symptoms. With regard to alcohol, it is often a good thing to begin with a small quantity of wine with food. Ultimately stimulants in larger quantities may be employed, and of these, old brandy and champagne are the best.

Camphor, in oil, injected intramuscularly, has a reputation as a cardiac stimulant, but any beneficial effect that it may have is probably not due to a direct action on the heart. More recently such compounds as *cardiazol* and *coramine*, which are soluble in water, have come into use, but their effect on the heart has not been proved.

Adrenaline.—The use of adrenaline hypodermically in Adams-Stokes syndrome is referred to on page 868. Intracardiac injection of adrenaline

may be tried in cases of complete arrest of the heart and respiration. Its chief use is in syncope during an operation. It has also been tried in cardiac failure from various causes, but its results here are uncertain. Artificial respiration should always be combined with it. The maximum dose should be 1 mg. (1 c.c. of 1-1000 solution), and the solution employed should not be more than 3 months old. No special needle is required; one for lumbar puncture or for inducing regional anæsthesia, with a syringe 2-5 c.c., suffices. The needle should be introduced in the fourth left intercostal space, close to the sternum, or the upper border of the fifth intercostal cartilage. After passing the needle perpendicularly for 2-3 cm., it should be turned slightly to the middle line. The right ventricle is reached, and on penetrating 4-5 mm. the cavity of the ventricle is entered. Care should be taken that the needle is certainly in the cavity of the ventricle, by withdrawing a little blood, before injecting the adrenaline. The drug should be injected slowly. Artificial respiration should be stopped while the injection is being made, but resumed immediately afterwards. After the heart has become re-animated, adrenaline intravenously may be employed.

Barium chloride.—The employment of this drug in Adams-Stokes syndrome is dealt with on page 868.

Atropine is supposed to paralyse the cardio-inhibitory terminations, and is indicated in some cases of Adams-Stokes syndrome (see p. 868).

Some believe that *iron* and *arsenic* are cardiac tonics, and, therefore, do not restrict the use of these drugs to cases of heart disease in which there is coexisting anæmia, but employ them in the early stages of cardiac failure. Iron, arsenic, strychnine and quinine are often serviceable during convalescence.

Glucose is of value in the treatment of congestive heart failure, and in conditions of circulatory collapse, such as may follow coronary thrombosis. It is a form of nutriment which is rapidly absorbed and easily metabolised. It may be given by the mouth, or intravenously. One pound of glucose dissolved in 2 pints of water and flavoured with orange or lemon juice forms a convenient concentrated solution, which may be given diluted to taste. For intravenous injection, a hypertonic solution is advocated, and 100 c.c. of a 30-50 per cent. solution may be administered.

Insulin, in conjunction with glucose, is held by some to be of value in congestive heart failure and also in angina pectoris. With regard to the former, most benefit is to be expected when there is evidence that a defect of myocardial nutrition underlies or aggravates the condition. Five units of insulin subcutaneously, followed in 15 minutes by 50 grammes of glucose or lævulose by the mouth, is given once daily. This may be continued for a week, the dose of both being then doubled if no improvement results. This form of treatment may be employed concurrently with the administration of digitalis. Respecting angina pectoris, see page 973.

The *bromides* are useful in cases of heart disease in which there is excitability or irritability of the nervous system, and in sleeplessness. The *iodides* are said to be of value in gouty conditions, hypertension, in arterial disease, in angina pectoris, and, most of all, when there is reason to believe that valvular, arterial or myocardial disease is the result of syphilis, and they may be taken for long periods of time; in the last group of cases they should be given in full doses (15 to 20 grains three times a day). *Mercury*

may with advantage be administered along with the iodides when the syphilitic infection is recent. With regard to arterial disease, while iodides may exert a beneficial influence in the earlier stages of the disease, it is practically certain that they are valueless in the later stages.

The *nitrites* may be tried in cases of hypertension, and in angina pectoris—in the latter even if unattended with high pressure. Nitrite of sodium, erythrol tetranitrate, mannitol nitrate, nitro-glycerine, and nitrite of amyl are most commonly employed.

Purgatives are of value when there are indications of distension of the right chambers of the heart, and dropsy, and also in cases of hypertension; salines, administered from half an hour to an hour before breakfast, are preferable.

Diuretics should be given in cases in which the amount of urine is diminished or dropsy is present. Among the best diuretics in heart disease are digitalis, squills, caffeine, theobromine, diuretin, theophylline, theophylline-sodium-acetate, scoparium, and the acetate or citrate of potash. The first named should be administered until full digitalisation is secured, and afterwards this should be maintained until the anuria or œdema has disappeared. A combination of the foregoing drugs is often more effective. Baillie's or Guy's pill, which consists of mercury, digitalis and squills, is a well-known combination. Among various prescriptions of this combination are:

R Pilulæ hydrargyri, Pulveris digitalis, Pulveris scillæ, Extracti hyoscyami, aa gr. i. Ft. Pil. One three times a day after meals.
R Pilulæ hydrargyri, grs. ii; Pulveris digitalis, gr. $\frac{1}{2}$; Pulveris scillæ, gr. i. Ft. Pil. One three times a day after meals. Another good combination is 5 grains of citrate of caffeine, 20 grains of citrate of potash, and a $\frac{1}{2}$ ounce of infusion of digitalis.

Novasurol, neptal and salyrgan are recently introduced compound mercurial preparations which have a very potent diuretic effect, and which are often of great value in the treatment of cardiac failure with dropsy. It is necessary to point out that owing to their high mercury content, they may give rise to symptoms of mercurial poisoning, such as stomatitis, severe colitis, with bloody diarrhœa, or hæmaturia. Novasurol is by far the most toxic, and its use has been largely abandoned in favour of salyrgan, which is safer, and little, if at all, inferior in diuretic potency. Salyrgan is best given intravenously. It is supplied in the form of a 10 per cent. solution, the dose of which is $\frac{1}{2}$ to 2 c.c. A preliminary dose of 1 c.c. is administered, and if no toxic symptoms supervene, doses of 2 c.c. may be repeated at intervals of 2 to 4 days. Occasionally local venous thrombosis follows the injections, but this may be avoided if the dose is diluted to 10 c.c. with sterile distilled water, and injected very slowly. The drug is best administered the first thing in the morning, in order to avoid the patient's sleep being disturbed. A profuse diuresis usually commences shortly after the administration of the drug and continues for 24 to 48 hours; and often 10 to 20 pints of urine may be passed within 24 hours. It may be used together with digitalis in the routine treatment of severe heart failure with diminished output of urine or dropsy, or it may be given weekly for long periods to ambulant patients whom the routine administration of digitalis fails to keep quite free from œdema. It is also of value in cases of adhesive pericarditis with

recurrent ascites. Salyrgan should be given when there is severe impairment of renal function or hæmaturia, but a moderate degree of albuminuria, such as is common in heart disease, does not contra-indicate its use. The diuretic effect of these mercurial preparations is increased if an acid-producing salt, such as ammonium chloride or nitrate, is also given by the mouth, 15 to 20 grains thrice daily in solution being the appropriate dose. When these mercurial diuretics are employed in cardiac failure, it is most important to restrict the daily intake of fluid to within 40 oz., and occasionally even 30 oz. Moreover, the total amount of urine passed each 24 hours should be carefully measured, and it is also advisable to weigh the patient at the commencement of the treatment and at weekly intervals, a reduction in weight being a valuable criterion of the efficacy of the treatment.

Lastly, it is usually advisable to alternate the variety of diuretics periodically.

OXYGEN.—Oxygen is sometimes of value in cases of cardiac failure, and the chief indications for its use are cyanosis and dyspnœa. It is usually required when pulmonary œdema or infarction, or hydrothorax interferes with the oxygenation of the blood in the lungs. Oxygen should be administered continuously, either through a nasal catheter or a special mask. The former is the simpler method and also is better tolerated by patients than a mask.

VENESECTION.—This method of treatment is often neglected when it might be employed to great advantage. It is of considerable value when there are indications of great distension of the right chambers of the heart—as, for example, severe dyspnœa, cyanosis, turgescence of the veins of the neck, and increased area of impairment of the percussion note to the right. ~~As a rule,~~ venesection should not be performed in patients suffering from aortic incompetence; in such cases it often does harm. The median basilic vein should be chosen, and a good quantity of blood—occasionally even up to 20 or 30 ounces—should be withdrawn; sometimes, however, 8 to 10 ounces are sufficient. If venesection is not practicable, 6 to 12 leeches over the right ventricle or liver are a substitute.

MASSAGE OF THE HEART.—This desperate measure finds its chief, if not only, indication in arrest of the heart during general anæsthesia. The best route for its application appears to be the subdiaphragmatic. The abdomen is opened, and the heart massaged from below the diaphragm. Artificial respiration should always be maintained at the same time. Not more than five minutes should be allowed to elapse before massage is employed after the heart has failed. The compression should at first be rhythmic, and if this method is not successful in ten minutes, it should be applied intermittently. Adrenaline into the external jugular vein is a useful adjunct.

TREATMENT WHEN CARDIAC FAILURE IS PRESENT

The amount of physical or mental effort should be reduced. In the slighter degrees of cardiac failure it may be sufficient if the patient remain in bed for a couple of hours every afternoon or one day a week, although it is usually better to commence treatment by keeping him continuously in bed for a short time. When heart failure is more pronounced the amount of

exertion should be reduced to a minimum, the patient being kept in bed for a period which may extend even to some months. When subject to nocturnal attacks of dyspnoea he may be most comfortable when supported by high pillows or a bed-rest, or he may not be able to breathe with comfort even in bed, and may prefer to sit up supported in a large easy-chair, perhaps leaning forwards and supporting himself with his arms on the back of another chair. In certain cases of cardiac failure, exercise in moderation, provided careful and detailed instructions be given as to its nature and extent, is of value.

In cases of cardiac failure, unaccompanied by nausea and vomiting, light solids form the best diet, and, as a rule, agree better than fluid food, being less likely to cause flatulence; the necessary mastication is also an advantage. Great care should be exercised to see that the patient does not take a larger quantity of food than he can comfortably digest. The food should be easily digestible. When cardiac failure is extreme, the amount of food should be considerably restricted, and only very small quantities at a time, at fairly frequent intervals, should be allowed. Biscuits, small thin sandwiches of potted meat, or small quantities of milk are not infrequently all that can be comfortably digested. Occasionally a pure milk diet, or a modified Salisbury diet, is best.

Other therapeutic measures appropriate to the condition should be employed until the requisite effects are obtained; the indications for, and the manner of employment of, each class of these in cardiac failure have already been fully described.

When there are indications of distension of the right heart, free purgation, the administration of diuretics, and venesection are indicated.

Special symptoms should be treated on the lines laid down later on.

The return of convalescence should be gradual, and the greatest care should be exercised. Convalescence from severe cardiac failure is sometimes aided at first by gentle massage, and, later, by carefully regulated and gradually increasing exercises—at first passive, and later active—before the patient is allowed to get up.

TREATMENT OF SYMPTOMS

Rest, and other measures and remedies previously described in detail, should be employed in the treatment of symptoms.

SLEEPLESSNESS.—The ventilation of the bedroom should receive attention, and, while the patient should be kept warm, the bedclothes should not be too heavy. It should be remembered that insomnia may be due to dyspnoea, and that in these cases the patient is sometimes troubled with "night starts" as he is falling off to sleep; the dyspnoea should be treated on the lines to be laid down later. Similarly, if hypertension be present, this should receive attention. The bromides or one of the other remedies mentioned on page 833 may be sufficient and suitable. Failing these, or as an alternative to such, I usually advise phanodorm, medinal, dial or paraldehyde. The last is an exceedingly valuable drug in many cases, especially when there is dyspnoea. If the patient is more restless or excited after taking the drug, it usually means that the dose has been too small. Trional and sulphonal are useful in cases in which insomnia occurs late at night. If these remedies fail, chloral hydras may be tried. This drug has the reputation of being a

dangerous remedy in heart disease, especially in myocardial degeneration, but I have used it very extensively and have never found this to be the case. It produces a refreshing sleep, and is especially useful when nocturnal dyspnoea or hypertension is present. It may be given in doses of 5-10 grains by the mouth, gradually increasing to 15 or even 20 grains if necessary, the dose being repeated in 2 hours if required, and the effects carefully watched all the time. Chloralamide (gr. xv-xlv) acts nearly as well as chloral hydras in some, although by no means in all, cases, and is supposed to be safer. Bromidia (3i or more) is also useful. If these drugs fail, resort should be had to opium or morphine, which are especially useful when there are accompanying restlessness and dyspnoea, and are particularly necessary in cardiac asthma and coronary occlusion. The hypodermic administration of morphine is much more efficacious in cardiac failure than when given orally, and there are disadvantages attending the latter method. It is well to commence with small doses, for example, $\frac{1}{4}$ th grain, and gradually to increase to $\frac{1}{2}$ th grain, or even more, until relief is obtained, the effects being carefully watched. Cyanosis is not an absolute contra-indication to the administration of chloral, opium or morphine. Speaking generally, these drugs should not be administered in those cases in which there is much bronchial secretion, or oedema of the lungs, or in Bright's disease; but in individual cases they may be tried if the first dose be very small, and the dosage be subsequently increased with great caution. Further, when there is much bronchial secretion, or oedema of the lungs, a sharp look-out must be kept to see whether the administration of the drug increases them; in such a contingency, atropine or strychnine should be administered in combination with the morphine.

CHRONIC VENOUS CONGESTION.—Treatment of systemic venous congestion consists in the restriction of the amount of daily fluid, dry diet, free purgation, the administration of diuretics, oxygen, and, if there are indications of great distension of the right chambers of the heart, venesection. In chronic venous congestion and passive oedema of the lungs, dry cupping is sometimes beneficial; the best time, as a rule, being when the patient desires to go to sleep.

OEDEMA.—The measures which are of particular value in the treatment of oedema are the restriction of the amount of daily fluid, free purgation, the administration of diuretics and, in the opinion of most, a salt-free diet. Restriction of the daily intake of fluid is most important. It should not exceed 40 oz. in the 24 hours, and occasionally even 30 oz. A watery diarrhoea is not necessarily a contra-indication to purgation, because it is frequently due to passive congestion of the intestinal mucous membrane. Besides the usual purgatives, calomel, and colocynth pill, or pil. hydrargyri, followed by a saline in the morning, may be given once or twice a week for a time. The subject of diuretics has been fully discussed on pp. 842, 843. In early dropsy, bandaging of the lower extremities is often useful, and this may be combined with massage. When the oedema does not disappear in spite of the measures mentioned, the mechanical removal of fluid should be considered. The means which may be employed are Southey's tubes, acupuncture, and scarification, the first two being better than the third. Whatever method be employed, strict aseptic precautions should be exercised. With regard to acupuncture, the dependent limbs and scrotum may be punctured by means of a sharp, broad surgical needle (which is grasped by the finger and thumb

from a quarter to half an inch from the point), and then wrapped in sterilised dressings to drain. If ascites or pleural effusion does not yield to other treatment, and causes embarrassment, the fluid should be withdrawn. With regard to the former, Southey's tubes or tapping may be employed; in the latter case, tapping is necessary.

DYSPNŒA.—If chronic venous congestion and œdema of the lungs, bronchitis, or gastric or intestinal flatulence be present, it should receive attention; and, similarly, fluid in the abdomen may require to be withdrawn. The exclusion of hydrothorax as a cause of dyspnœa should always be a matter of consideration, and, when present, paracentesis thoracis should be performed. Diffusible stimulants, oxygen and strychnine should be tried. The latter may be given in full doses in the evening.

CARDIAC ASTHMA.—Diffusible stimulants and vaso-dilators—such as amyl nitrite, nitroglycerine, erythrol tetra-nitrate, or sodium nitrite—are sometimes efficacious. Failing these, oxygen should be employed. If this fails, chloral may be tried, and, if this is not successful, morphine with atropine, or atropine with 3-5 minims of 1-1000 solution adrenaline, hypodermically. If there are indications of great distension of the right chambers of the heart, venesection is indicated.

PULMONARY ŒDEMA.—Dry cupping is sometimes beneficial in chronic pulmonary œdema. If an attack of acute pulmonary œdema occurs, a hypodermic of morphine, gr. $\frac{1}{3}$ rd, with atropine gr. $\frac{1}{100}$ th, should be given. Oxygen should also be employed, unless it is found to cause restlessness. If there should be indications of great distension of the right chambers of the heart, venesection should be performed.

COUGH.—The cause of the cough, which may be œdema of the lungs or hydrothorax, should after investigation be suitably treated, and relief may be sometimes obtained by the administration of hot drinks, and the application of a large mustard and linseed poultice over the bases of the lungs. A linctus may be necessary.

HÆMOPTYSIS.—Hæmoptysis is only rarely a serious accompaniment of heart disease, and may be combated by rest, together with the administration of calomel and saline purgatives. It may be necessary, however, to supplement these measures by the administration of morphine. Venesection or leeching is advocated by some writers in severe cases.

SYNCOPE.—It has been noted on page 826 that this complication may be cardiac or vaso-motor in origin. The treatment of syncope is divided into prophylactic and immediate. Heated rooms, crowds and prolonged standing should be avoided. The various therapeutic measures described elsewhere, including those for paroxysmal tachycardia, Adams-Stokes syndrome, and subnormal blood-pressure may be indicated. If syncope actually occurs, the patient's head should be lowered and the clothes loosened at the neck. Plenty of fresh air is indicated. Diffusible stimulants, such as ether, ammonia or brandy should be given by the mouth. Strychnine (gr. $\frac{1}{30}$ - $\frac{1}{20}$ th), coramine, or cardiazol-ephedrine, may also be administered subcutaneously or intramuscularly. If these measures fail, pituitrine ($\frac{1}{2}$ -1 c.c.), or in the case of pregnancy, pitressin ($\frac{1}{2}$ c.c.), intramuscularly.

PALPITATION.—The possible causes of palpitation should be carefully considered and adequately treated; among these, gastric and intestinal dyspepsia and toxic agents are especially to be noted. Rest is indicated in

some cases, and a belladonna plaster applied to the præcordium is sometimes efficacious. If these measures fail, sedatives (see p. 833) may be given a trial.

TACHYCARDIA.—We should first of all review the ætiology of the condition, with a view to treatment. The treatment of tachycardia in organic heart disease has, for the most part, been dealt with in the general consideration of cardiac failure. The question of toxic agents, such as tea and tobacco, febrile states, neurasthenia, and hysteria, as possible causes of tachycardia, should always be considered. Sedatives (see p. 833) and belladonna appear to be of value in some cases of tachycardia.

CARDIAC PAIN.—As in the case of palpitation, we should first of all consider the possible causes of cardialgia. Rest is especially indicated when it is obviously due to overstrain or dilatation. Iodide of potassium is sometimes efficacious, even when the pain is not associated with hypertension. A belladonna plaster, or linim. bellad. c. chlorof., applied to the præcordium may be beneficial; while sometimes—especially in acute inflammatory conditions—the employment of hot fomentations or poultices, an ice-bag or Leiter's coil, a mustard leaf, or leeches may afford relief. If these measures fail, sedatives (see p. 833) may be administered, and in the event of their not being successful it may be necessary to resort to opiates, nepenthe or tincture of opium being tried at first, while if the pain still continue morphine may become necessary.

VOMITING.—Milk is, in the majority of cases, the best food, to which sodium citrate (15 grains to each 10 ounces) may be added. If milk be not tolerated, peptonised milk, whey, albumin water, milk gruel, koumiss, or strong meat essences may be sipped, the patient not being allowed any solid food. A brisk purge should be administered, and bismuth with hydrocyanic acid may be given. Counter-irritation over the epigastrium is occasionally of some help for the relief of vomiting. If, in spite of these measures, the vomiting still continue, all food, and even water and drugs, by the mouth should be stopped, and resort be had to rectal feeding. The great advantage in these cases of rectal feeding with milk pancreatized for at least 24 hours is not sufficiently appreciated.

Having now discussed the various therapeutic measures which may be applicable to any form of cardiac disorder, these need not be again referred to when we come to consider the treatment of the individual cardiac affections: in this way much repetition will be saved.

FREDERICK W. PRICE.

FUNCTIONAL DISORDERS OF THE HEART

By functional disorders of the heart are meant those which occur independently of any structural change, whether of the valves, the myocardium, or the arteries; they are merely disorders of function, no organic lesion being necessarily present. It should be remembered, however, that any variety of functional disorder may be found in association with, though independent of, organic disease, especially if cardiac failure be present; and, further, that a persistent functional disorder may terminate in organic disease, although not necessarily so. Some writers deny the existence of functional disorder

of the heart altogether, being of opinion that in every case some structural change not only exists but accounts for the malady. Such a view is, in my opinion, untenable. I wish to emphasise at this stage, however, that in a not inconsiderable percentage of cases a diagnosis of functional disorder is erroneously made owing to the fact that the existence of organic disease has not been detected, because the examination has been conducted either with insufficient care or has been incomplete. As far as my experience goes, this applies especially to four classes of cases, namely: (1) Those with enlargement of the heart due to chronic myocardial disease, especially chronic interstitial myocarditis, unaccompanied by valvular disease; (2) cases of arterial disease; (3) less frequently, cases of mitral stenosis; and (4) still less frequently, cases of chronic adhesive pericarditis.

Taking chronic myocardial disease first, I have been surprised at the comparative frequency with which these cases are overlooked, due, in my opinion, to a lack of appreciation of the great importance of determining accurately the size of the heart, especially in cases in which the apex-beat is either faint or absent; and also to a lack of knowledge of the size of the normal heart in persons of different size and weight and age. A combination of the existence of subjective symptoms during or after physical exertion, enlargement of the heart, and an absence of physical signs indicative of a valvular lesion are of the utmost importance in the diagnosis of chronic myocardial disease. With regard to arterial disease, the importance of examining the walls of other arteries than the radial should be remembered. How frequently is arterial disease excluded as the result merely of an examination of a short length of the radial artery alone! Not only the radial, but at least the brachial and temporal arteries should be examined. Moreover, examination of the retinal arteries with the ophthalmoscope and of the aorta with X-Rays will often provide evidence of arterial disease when the peripheral vessels appear to be little, if any, affected. With regard to mitral stenosis, the lesion is often unrecognised, because the locality of the characteristic murmur is not infrequently very limited, or because of an omission to examine the patient both in the standing position and on lying down, and before and after exercise, or because in some cases there is from time to time a complete absence of a thrill and murmur. I would emphasize the importance of a searching examination for organic disease of the valves, the myocardium and the arteries in all cases which on first consideration might be regarded as being merely functional.

Among functional disorders may be included palpitation, tachycardia, bradycardia, irregular action of the heart, paroxysmal tachycardia, "irritable heart"—including "soldier's heart," primary cardiac overstrain, and cardiac pain. No doubt some of these disorders may be either functional, or due to organic disease. With regard to irregular action of the heart, it depends upon the type. It is almost universally agreed that sinus irregularity is always functional. Extra-systoles may or may not be due to some structural change in the myocardium. It is true that cases of auriculo-ventricular block have been recorded in which there was an absence of any demonstrable lesion of the junctional tissue; but in some of these the vagus was found to be affected. In the vast majority of cases, auricular fibrillation and auricular flutter are indicative of some myocardial change. With regard to what is called "soldier's heart," as the result of a detailed examination of a large

number of cases, I am of opinion that the affection is sometimes due to chronic interstitial myocarditis, frequently in association with arterial disease, which has not been diagnosed. I am equally certain, on the other hand, that primary cardiac overstrain may occur in persons with previously sound hearts, and even in those who have been properly trained. A history of excessive physical exertion resulting in primary cardiac overstrain is sometimes not obtained because of insufficient care in taking the history of the case.

It is not my purpose to deal with the ætiology of functional disorders of the heart in general, but I would emphasise the importance of always remembering the possibility of toxic conditions affecting the heart. This may occur without producing structural changes. Such toxic conditions may be brought about by acute infective diseases, focal sepsis, Graves' disease, pulmonary tuberculosis, and the excessive use of tea, coffee, tobacco and alcohol.

PALPITATION

By palpitation is meant the consciousness of the cardiac impact against the chest-wall, and with this there is frequently, but not always, an increase in rate. The term, as used here, does not include the sensations which may be present in extra-systoles, auricular fibrillation, auricular flutter, or paroxysmal tachycardia; it will further be restricted to those cases in which the consciousness of the cardiac impact occurs in attacks.

Ætiology.—While palpitation may occur in organic disease of the heart—valvular or myocardial—it should be remembered that it is probably more frequently and most characteristically met with apart from organic disease. It is more common in females than in males. The condition is often reflex in origin, as, for example, when the result of dyspepsia—particularly those forms of it which are attended with flatulent distension of the stomach or colon, and in uterine disorders. Among other causes are excessive indulgence in the use of tea, coffee, alcohol, or tobacco; conditions which tend to produce exhaustion or undue excitability of the nervous system, among which may be enumerated puberty, the period of menstruation, the menopause, neurasthenia, hysteria, mental excitement or overstrain, exhausting illnesses, and following the acute fevers. The immediate cause of an attack is frequently emotion or excessive physical exertion.

Symptoms.—The attack may last from a few seconds to a few hours. It is usually, though not always, gradual in onset, and it passes off gradually. The subjective symptoms vary from a sensation of a gentle impact in the slightest attacks, to the consciousness of a violent one against the chest-wall, accompanied by a sense of great distress, and even associated with actual pain in the præcordium in the severer forms of the attack. In some instances there is a sense of faintness, and more rarely the fear of impending death. Complaint is sometimes made of flushing of the face, tinnitus aurium, a sensation of throbbing in the head, and giddiness. The pulse-rate is, as a rule, increased, though in some cases there is an absence of tachycardia; it is increased by physical exertion, which is not the case in paroxysmal tachycardia. The pulse may be of moderate or only small volume, and its character may resemble that of the *pulsus celer*. The large arteries, such as the carotid, may exhibit marked pulsation. The apex-beat is found

to be in the normal position, and its area and force are generally much increased. On percussion, the area of cardiac impairment shows no increase in size, unless valvular or myocardial disease be present, while on auscultation, the cardiac sounds are found to be abnormally loud, clear, and ringing in character, and the second sound at the base much exaggerated. Excepting in cases of organic disease of the heart or anæmia, as a rule, no murmur is audible, although occasionally an apical systolic murmur, soft in character, may be heard during the attack. In dyspeptic patients, complete or partial relief may coincide with the eructation of a large quantity of gas. A sense of exhaustion is usually complained of after the paroxysm has passed off.

Prognosis.—The prognosis is good, if no organic disease be present, although it may be difficult to eradicate the cause of the condition.

Treatment.—This has already been considered.

CARDIAC PAIN

As has already been pointed out, pain in the præcordium may not only occur in organic disease of the heart, but is also frequently met with apart from organic disease, especially in females. It is often reflex in origin, as, for example, when the result of dyspepsia—particularly those forms of it which are attended with flatulent distension of the stomach or colon, and in uterine disorders. Among other causes are primary cardiac overstrain; toxic conditions, such as occur in influenza and diphtheria, and as the result of excessive indulgence in the use of tea, coffee, tobacco, or alcohol—neurasthenia, hysteria, emotional states, and sexual excess.

Treatment.—This has been discussed previously.

TACHYCARDIA

Definition.—By the term tachycardia is meant frequent action of the heart. It will here be used in a restricted sense, not including the frequent action which is often present during attacks of palpitation—which has already been described, or that due to an abnormal rhythm—which will be discussed later on.

Ætiology.—The condition may be physiological. In some perfectly healthy individuals the normal cardiac rate is always frequent, and has been known, although very rarely, to average 120 a minute. It is difficult, therefore, to decide when an increase of the cardiac rate in an individual is pathological; in this connection, a record of the past history is of value.

The pathological form of tachycardia may be the result of the excessive use of alcohol, tobacco, tea, and coffee, focal sepsis, pulmonary tuberculosis, Graves' disease, most forms of cardiac disease, primary cardiac overstrain, states of exhaustion, acute and subacute inflammatory conditions, pyrexia, neurasthenia and emotional states, certain organic diseases of the nervous system, reflex irritation from uterine or ovarian disease, the use of certain drugs, such as atropine, and as a sequel of influenza.

In the pathological form of the condition, the increase in the cardiac rate may only be induced by change of posture or other forms of physical exertion; or it may be persistently above the normal.

In contra-distinction to tachycardia due to an abnormal rhythm, the

only abnormality in polygraphic and electro-cardiographic curves is the acceleration of the cardiac rate.

Treatment.—This has already been described.

BRADYCARDIA

Definition.—By the term bradycardia is meant infrequent action of the heart. It must be distinguished from infrequency of the *pulse-rate at the wrist*, since the latter also includes ventricular extrasystole which is so feeble that the wave fails to reach the wrist. The term bradycardia may be used in two different senses: it may be restricted to infrequent action of the heart as a whole, the auricular rate being diminished *pari passu* with that of the ventricle—sinus bradycardia; or it may be employed to include also cases of infrequency of the ventricular rate alone, the auricular rate being unaffected—ventricular bradycardia, which group includes partial and complete auriculo-ventricular block, some cases of auricular fibrillation, and some cases of auricular flutter. The term will be employed in the former sense.

Ætiology.—Bradycardia may be physiological, especially in males. In some perfectly healthy individuals the normal pulse is always infrequent, a pulse-rate of 50 not being very uncommon, and, indeed, cases have been recorded of a pulse-rate of 40 in a healthy individual. Further, it must be noted that as age advances the rate of the heart normally becomes less frequent.

The pathological form of the condition, which is found more frequently in males, may be the result of some form of cardiac disease—especially aortic stenosis and fatty degeneration of the myocardium, coronary disease, and primary cardiac overstrain; states of collapse or exhaustion, and during the convalescence of acute infective diseases, especially influenza, diphtheria, pneumonia, typhoid and typhus; toxic conditions, such as jaundice, diabetes, uræmia, influenza and diphtheria, and the use of certain drugs, such as digitalis, muscarine, opium, coffee, and tobacco; hypothyroidism; certain diseases of the nervous system; diseases of the digestive system, such as chronic dyspepsia, gastric dilatation, ulcer, and cancer; in the puerperal state; and occasionally in diseases of the urinary or respiratory system, and in sunstroke.

Sino-auricular block is a very rare cause of bradycardia.

IRREGULAR ACTION OF THE HEART

The subject of irregular action of the heart is of very great practical importance. Formerly it was notoriously a source of perplexity and difficulty to the clinician. It was known that irregularity of the pulse might, on the one hand, signify definite and even serious impairment or disease of the heart, or, on the other hand, that it might be of no practical importance. It was not possible, however, to determine the significance of the irregularity in any given case, because there were no means of differentiating the types of irregularity, or what any particular type signified. The employment of the clinical polygraph and of the electro-cardiograph has changed all this, and the problem has been solved; for we are now able to classify almost every case of irregular action of the heart into types, and we know what each type signifies. I would emphasise that the work of elucidation having

been accomplished by means of the clinical polygraph and the electrocardiograph, it is not now necessary to employ either of these instruments in the great majority of cases, the use of a sphygmograph being sufficient, and in a large proportion merely palpation and auscultation. For example, by means of the aid of palpation and auscultation alone it is almost always possible to determine whether intermission of the pulse occurring during the course of an acute infective disease is due to an extra-systole failing to reach the wrist, or to partial auriculo-ventricular block—a point of great prognostic importance.

All cases of cardiac irregularity, apart from comparatively rare exceptions, fall into one of six groups: (1) What is called sinus irregularity; (2) irregularity due to premature contraction of extra-systole; (3) irregularity due to heart block; (4) irregularity due to pulsus alternans; (5) irregularity due to auricular fibrillation; and (6) irregularity due to auricular flutter.

It may be advisable to describe here what is meant by the terms "intermittent" pulse or a "dropped beat" "pulsus bigeminus" or "coupling of the beats," and "pulsus trigeminus."

Intermission of the pulse is a form of irregularity which is not uncommon. By it is meant a condition in which the normal rhythm of the pulse is interrupted, either occasionally or more frequently, either at regular or irregular intervals, by an abnormally long pause during which no wave is felt at the wrist, a beat being missed. *It is of great importance to understand how intermission of the pulse is caused, especially from the point of view of prognosis.* By far the commonest cause is a premature contraction of the ventricle ("extra-systole") which is so feeble that the wave fails to reach the wrist; the next most common cause is partial heart-block, while the condition is occasionally due to sinus irregularity, and very rarely to sino-auricular block. The differential diagnosis between extra-systole and partial heart-block is fully discussed under extra-systole. The differential diagnosis also between occasional dropped beats due on the one hand to sinus irregularity and on the other to partial heart-block is discussed under heart-block.

By *pulsus bigeminus* or *coupling of the beats* is meant a condition in which the pulse-beats occur regularly in pairs, for long or short periods. The paired beats may occur at regular intervals, or at irregular intervals, and some writers restrict the term *pulsus bigeminus* to the former condition, and the term *coupling of the beats* to the latter. When the paired beats fall at regular intervals, the commonest cause is the occurrence of extra-systoles, usually ventricular, in cases in which the fundamental or sinus rhythm is otherwise maintained; either a single extra-systole with its succeeding compensatory pause occurring regularly after each normal beat (Fig. 27), or such occurring after every two normal beats, the premature contraction in the latter case, however, being so feeble that no waves reaches the wrist. The next most common cause is partial heart-block, when the ventricle fails to respond to every third beat of the auricle (Fig. 28). A rare cause is sino-auricular block, in which the auricle fails to respond to every third impulse generated at the sinus. When the paired beats fall at irregular intervals, the cause is the occurrence of a ventricular extra-systole occurring regularly after each normal ventricular contraction in cases of auricular fibrillation; this may occur independently of the action of digitalis, although it is usually due to it (Fig. 43).

By *pulsus trigeminus* is meant a condition in which the pulse-beats are grouped in threes. The causes of this condition are: (1) the occurrence of extra-systoles—either a single extra-systole with its succeeding compensatory pause occurring regularly after every two normal beats, or such occurring

FIG. 27.—Pulsus bigeminus, due to a single extra-systole with its succeeding compensatory pause occurring regularly after each normal beat.

after every three normal beats and failing to send a wave to the wrist; (2) partial heart-block, when the ventricle fails to respond to every fourth beat of the auricle; and, rarely, (3) sino-auricular block, in which the auricle fails to respond to every fourth impulse generated at the sinus. As pulsus

FIG. 28.—Pulsus bigeminus, due to partial heart-block, the ventricle failing to respond to the stimulus from the auricle at A'.

bigeminus and pulsus trigeminus are met with in conditions other than extra-systole, they are not pathognomonic of the latter condition. The distinguishing features between pulsus bigeminus or pulsus trigeminus, due on the one hand to extra-systole and to partial heart-block on the other hand, may be established, with a view to differential diagnosis, in the same way as in the case of an intermittent pulse.

“IRRITABLE HEART”

This term may be used in two ways, namely, (1) the “irritable heart of soldiers,” and (2) a condition which is sometimes met with during adolescence. The first of these will be discussed later. The second condition is met with more especially in badly developed subjects, and is often associated with an unstable nervous system, auto-intoxication, and dyspepsia. It may or may not have been brought on by excessive or injudicious physical exertion. The symptoms and diagnosis do not differ from those which obtain in the “irritable heart of soldiers.” The prognosis is good, the patient improving as physical and mental development proceeds. With regard to treatment, a searching inquiry should be made for toxic conditions. The patient should rest before and after meals, all food should be thoroughly masticated, the amount of fluid to be taken with food should be restricted, and digestive disorders treated if present. Breathing exercises, graduated exercises, and all other agencies which tend to physical and mental development, should be tried. Otherwise, the treatment is the same as that of the “irritable heart of soldiers.”

SINUS IRREGULARITY

It has already been pointed out that excitability of the heart is most marked in the remains of the sinus venosus at the orifices of the great veins, and that the rhythm of the sinus governs the rhythm of the remaining segments of the heart. Further, it has been shown that the heart possesses

FIG. 29.—Simultaneous tracings of the respiration and the radial pulse, from a healthy boy aged 14, showing sinus irregularity.

the power of contracting and dilating independently of any extrinsic nervous influence; but, at the same time, the activity of the various functions of the muscle-fibres is under nervous control. While normally the rhythm of the sinus is a fairly regular one, in by no means a small percentage of individuals the rhythm is not regular. In all probability this irregularity is of vagus origin, due to an unusual susceptibility of the vagus centre to

FIG. 30.—Simultaneous tracings of the jugular and radial pulses, from a healthy boy aged 7, showing sinus irregularity.

impulses from distant parts, and these impulses being transmitted reflexly to the heart. The chief characteristic of sinus irregularity is the variation in the length of the diastolic period of the cardiac cycle, the systolic period remaining constant. The irregularity, which may be slight or marked, diminishes, and may even disappear with an increase, while it is apt to increase or return with a diminution, of the cardiac rate.

Ætiology.—Sinus irregularity is much more frequently met with in the young, being indeed fairly common in young adults; but it may occur at all

ages. There is a greater tendency to sinus irregularity after a febrile illness, and it may be first noticed then. *There is usually a definite relationship to respiration.* The irregularity is most marked during slow respiration, and may indeed only be noted on deep breathing. The rate of the heart usually gradually quickens during full inspiration, and gradually lessens during full expiration; but while generally the rate of the pulse waxes and wanes with respiratory movements, in some cases there is an abrupt slowing of one or two beats with expiration. Sinus irregularity may occur during the administration of digitalis, and even the act of swallowing may produce it—the heart-rate during the act being quickened for a few beats, followed by a reduction in the rate.

Symptoms. Usually there are no subjective symptoms of the condition; but very rarely the abnormal pause between any two beats of the heart is so long that symptoms of cerebral anæmia, such as giddiness or syncope, occur. On auscultation, the interval between the first and second sounds is found to be constant, while the varying length of the diastolic interval can be detected. If a tracing of the radial artery be taken, the intervals between the beats will be found to vary, but the actual variations are not numerous, while the pulse-beats are of equal or nearly equal size (Figs. 29 and 30). A polygraphic tracing (Fig. 30) and an electro-cardiogram (Figs. 79–81) show that a ventricular contraction follows each auricular contraction in the usual way, and that the whole heart is affected by the irregularity.

Diagnosis.—A diagnosis may be made by auscultation, or by a study of a sphygmogram, or of a polygraphic or electro-cardiographic record. When irregularity of the cardiac action is found to be definitely related to respiration, it is in all probability of the sinus type.

Prognosis.—There is no reason to suppose that sinus irregularity is either indicative of an impaired heart, or that it adds to the gravity of any diseased cardiac condition which may be present. The condition itself, therefore, may be entirely disregarded, and the prognosis based upon any other abnormal signs which may exist.

Treatment.—No treatment of this condition is required.

THE EXTRA-SYSTOLE

By extra-systole is meant the premature contraction of the auricle (auricular extra-systole), or of the ventricle (ventricular extra-systole), or of both chambers together (auriculo-ventricular or nodal extra-systole), while the fundamental or sinus rhythm is otherwise maintained in most cases. Usually the extra-systole is followed by a long pause (compensatory pause). Rarely the premature contraction occurs between two normal beats (interpolated extra-systole). Two or more premature contractions of the auricle or ventricle may follow one another (multiple extra-systoles).

It has been shown that, while normally the stimulus for contraction arises in the sinus part of the auricle, if any other portion of the remains of the primitive cardiac tube becomes more excitable the stimulus for contraction arises at that point, and, for this reason, the different parts of the heart are capable of independent contraction. In abnormal

conditions the auricle, some part of the auriculo-ventricular junctional tissues—either the auriculo-ventricular node, or the auriculo-ventricular bundle above its division into two branches—or the ventricle below the division of the auriculo-ventricular bundle into two branches, may become temporarily more excitable than the sinus, in which case the stimulus for contraction starts at that particular point, the result being that a contraction takes place before the anticipated time. If the stimulus starts in the auricle, there is a premature contraction of that chamber; if in the auricular-ventricular junctional tissues there is a premature contraction of both auricle and ventricle together; while if it starts in the ventricle there is a premature contraction of the ventricle. In each case the sinus rhythm remains unaltered. It will thus be seen that an extra-systole indicates that some portion of the heart below the sinus is temporarily more excitable than the sinus.

Extra-systoles may appear at long, or at frequent irregular intervals, or regularly after each beat, or after every second or third, or more normal beats, or in paroxysms, the last being an infrequent cause of paroxysmal tachycardia. Of the three varieties the auricular and ventricular are the most important from the clinical point of view; the ventricular is the most common; all of them, however, may occur in the same subject.

THE VENTRICULAR VARIETY OF EXTRA-SYSTOLE.—We may take this variety for the purpose of illustration. While the chambers of the heart are contracting in the normal fashion, a premature contraction of the ventricle takes place, this arising independently of a stimulus from the auricle, which maintains its usual rhythm and contracts as the result of the normal stimulus from the sinus. The exact time at which the premature contraction of the ventricle takes place is either immediately before the systole of the auricle (Fig. 31), or—as is usually the case—synchronously with it, or after it, but prior to that point of time at which it would have occurred if this had been in response to a stimulus received from the auricle in the normal way. In most cases the succeeding impulse from the auricle fails to cause a contraction of the ventricle; for this reason the pause which follows the premature contraction is abnormally long, being called the *compensatory pause*. When this prolonged diastole and the preceding shortened diastole together equal in time two normal cardiac cycles, the compensatory pause is said to be *complete*. Since during the prolonged pause the ventricle has had an unusually long period in which to fill and recuperate, the pulse-beat immediately following a compensatory pause has often a greater amplitude than on other occasions. Sometimes, more especially when the cardiac rate is slow, a ventricular extra-systole occurs so early in the cardiac cycle that the ventricle does contract in response to the normal stimulus which is transmitted from the auricle immediately after the premature contraction; in this way a premature contraction is interpolated between two normal beats. This form of the extra-systole is called "*interpolated*" (Fig. 32).

On auscultation, in the vast majority of cases, two heart-sounds are synchronous with each extra-systole, these forming with those of the preceding normal contraction a group of four sounds. Sometimes, however, the extra-systole occurs early in diastole, and before the cardiac muscle has had sufficient time to recover fully from the preceding systole, in which event the premature contraction is so feeble as to fail to open the aortic valves, and

only the first sound is heard; in this way a group of three sounds becomes audible. Very rarely the premature contraction is so feeble as not to produce any cardiac sounds whatever.

The amplitude of the pulse-wave of an extra-systole is not so great as that of a contraction occurring at a normal interval, because the heart muscle

FIG. 31.—Simultaneous tracings of the jugular and radial pulses, showing a ventricular extra-systole at *Ex.s.* The usual rhythm of the auricle is maintained. The extra-systole in the jugular tracing is represented by the wave *c'*, immediately before the systole of the auricle. The compensatory pause is complete.

has not had time to recover from its previous effort. The earlier an extra-systole occurs in the diastole, the more feeble it is; it may be so feeble that no wave is felt at the wrist, so that there is simply an abnormally long pause, resulting in what is called a “dropped beat” or an “intermittent” pulse; as has been already noted, an extra-systole which fails to reach the wrist is, indeed, the most usual cause of an intermittent pulse. If a single extra-systole with its succeeding compensatory pause occurs regularly after

FIG. 32.—Simultaneous tracings of the jugular and radial pulses, showing an interpolated ventricular extra-systole (*c'* and *r'*), represented in the diagram by the downstroke +. The downstrokes in the space *As* represent the auricular waves (*a*) in the jugular, and the downstrokes in the space *Vs* represent the carotid waves *c*, and the slanting lines connecting them represent the *a-c* interval (Mackenzie).

each normal beat, then the beats at the cardiac apex occur in pairs, as also do the pulse-beats, the condition being called *pulsus bigeminus* (Fig. 27). Similarly, if a single extra-systole with its succeeding compensatory pause occurs after every two normal beats, then the apex-beat occurs in threes, as also do the pulse-beats, the condition being known as *pulsus trigeminus*; but if the premature contraction is so feeble that no wave reaches the wrist, the pulse-beats are paired.

If a polygraphic record of a case of ventricular extra-systole (Fig. 31) be analysed it will be found that, as the normal rhythm proceeds as usual the *a* wave appears at regular intervals; each *a* wave is followed by a

c wave, except when an extra-systole occurs, when the *c* wave either precedes the *a* wave, or—as is more commonly the case—occurs synchronously with it, in which case the amplitude of the wave is correspondingly increased.

AURICULAR VARIETY OF EXTRA-SYSTOLE.—In this variety there is a premature contraction of the auricle, the stimulus arising in the wall of the auricle prior to the normal stimulus from the sinus. The premature contraction of the auricle is usually followed by a premature contraction of the ventricle, following the usual transmission of the stimulus from the auricle along the auriculo-ventricular bundle. Not infrequently, in the case of extra-systole the stimulus from auricle to ventricle travels slowly, so that the *a-c* interval is lengthened (Fig. 33), and the prematurity of the ventricular systole is consequently not so great as that of the auricle; in this way the compensatory pause is shortened. In some instances the contraction which immediately follows the extra-systole takes place rather earlier than the normal interval, this being probably due to the unusual length of the rest period; in this way there is further encroachment upon the compensatory

FIG. 33. --Simultaneous tracings of the jugular and radial pulses, showing auricular extra-systoles, marked A.X.S. in the sphygmogram, and *a'c'v'* in the jugular tracing. The *a-c* interval of the premature beat is more than $\frac{1}{4}$ th second; with the rhythmic beats it is normal.

pause. This is less marked in the case of the second contraction, and it disappears within a few cycles. Sometimes there are variations in the rate of transmission of these auricular premature contractions to the ventricle.

Occasionally the stimulus from the auricle does not reach the ventricle at all, and no premature contraction of this chamber takes place, in which event the premature contraction of the auricle is not followed by a premature contraction of the ventricle, the condition being known as “blocked auricular extra-systoles.” In these cases a long pause is to be noted in the sphygmogram. As in the case of the ventricular variety, an auricular extra-systole is followed by a lengthened pause; but, with rare exceptions, this compensatory pause is not complete. In some cases, however, the compensatory pause is complete.

If a polygraphic record of a case of auricular extra-systole (Fig. 33) be analysed, it will be found that each *c* wave is preceded by an *a* wave, while there is a premature *a* wave and a premature *c* wave, sometimes with an increased *a-c* interval, and an alteration of the relative position of the beats following the extra-systole.

AURICULO-VENTRICULAR OR NODAL VARIETY OF EXTRA-SYSTOLE.—In this variety the stimulus for premature contraction originates in some part of the auriculo-ventricular junctional tissues, travelling upwards into the auricle and downwards into the ventricle, and giving rise to a premature and simultaneous contraction of both auricle and ventricle. The premature ventricular contraction more or less coincides with that of the auricle, but this is by no means absolute; the contraction of both chambers may be absolutely synchronous (Fig. 34), or the ventricular systole may begin after or before that of the auricle. When the auricular contraction occurs before that of the ventricle, the period of time between the contraction of the upper and lower chambers is shortened. The compensatory pause may or may not be complete.

In a tracing of the jugular vein from a case of auriculo-ventricular extra-systole (Fig. 34) there is prematurity of the *a* wave, and also of the *c* wave; when the premature contraction of the chambers is synchronous both waves are combined, in which case the amplitude of the wave is increased; when the auricular contraction occurs before that of the ventricle, the *a* wave precedes the *c* wave, but the *a-c* interval is diminished to about 0.10 sec.

FIG. 34.—Simultaneous tracings of the jugular and radial pulses, showing auriculo-ventricular extra-systoles, marked *E.s.* in the sphygmogram, and *a' c'* in the jugular tracing. The premature ventricular contraction practically coincides with that of the auricle.

In the ventricular and auriculo-ventricular varieties of extra-systoles, in contrast with the "double" venous pulsation in the jugular vein which may be visible in the case of the auricular variety, there is usually an unduly large "single" pulsation coincident with the premature contraction; this is due to the contraction of the upper and lower chambers of the heart occurring synchronously, the result being that the auricle, instead of discharging its contents into the ventricle, does so into the *venæ cavæ*.

Paroxysms of extra-systoles of auricular origin may occur, and may give rise to short paroxysms of tachycardia, with a regular pulse, or to irregularity of the pulse rhythm when the response of the ventricle to auricular contraction is at irregular intervals. Paroxysms of extra-systoles of ventricular origin may also occur (Fig. 98); as a rule these only persist for a few cardiac cycles.

Ætiology and Pathology.—Extra-systoles may be met with at any age, but they are much more frequent in the middle-aged and elderly than in the young. They are rare during the first decade of life. Extra-systoles are of more common occurrence in men than in women, and are also more usual in the subjects of organic heart disease than in those who are not, and are more frequent in myocardial degeneration than in valvular disease. But there is

a large group of cases in which extra-systoles are present without any other manifest cardiac abnormality. They are to be found, for example, in persons with a history of rheumatic infection, the victims of tobacco poisoning, in digestive disturbances, supernormal blood-pressure, neurasthenia, and as a result of the administration of certain poisons, especially digitalis and aconitine; while in a considerable proportion of cases there is no ascertainable cause.

Extra-systoles indicate that at the time of the premature contraction some portion of the myocardium below the sinus is more excitable than the sinus. This may or may not be due to some structural change in the myocardium; it may, for example, be caused by poisoning of the heart wall without structural damage.

Subjective Symptoms.—An individual in whom extra-systoles occur may be quite unconscious of their presence. On the other hand, he may experience certain sensations, which may cause worry and anxiety, particularly if he have retired to bed, and for this reason it is most important that the nature of the complaint should be recognised. The patient may experience a sensation of fluttering in the chest when a premature beat occurs: or he may be conscious of the long pause and complain of intermission of the pulse, or that the "heart stops"; or the contraction of the heart following the pause may be accompanied by the consciousness of a thud or shock in the region of the heart, sometimes followed by a feeling of exhaustion. The patient may complain of a sensation of a "catch in the breath," or of "gripping in the throat." Very rarely, during a prolonged pause, faintness, sweating and actual syncope may take place, and the anxiety of the patient may be great.

Diagnosis.—Extra-systoles may be recognised with certainty by means of the clinical polygraph or the electro-cardiograph. *But it is important for the practitioner to recognise that in the great majority of cases a correct diagnosis can be made simply by palpation and auscultation.* The normal rhythm of the heart is disturbed by the occurrence of a premature beat in the radial pulse and at the cardiac apex, followed by an abnormally long pause. The auscultatory signs have already been noted; they are of great diagnostic value. When, on palpation of the radial artery, an apparently otherwise regular pulse is sometimes interrupted by an unusually long pause, it should suggest either an extra-systole which is so feeble that no wave is felt at the wrist, or partial heart-block. *When extra-systole is responsible for this unusually long pause a premature beat can be detected at the cardiac apex, and on auscultation one or two heart sounds will, in the great majority of cases, be audible during the early part of the pause, because the ventricle has contracted; whereas in the case of partial heart-block, there will be absence of an apex-thrust and of heart-sounds during the pause, because the ventricle has failed to contract.* Further, in these cases of extra-systole, a wave is usually present in a sphygmographic tracing, and a premature contraction is always visible in a tracing of the apex-beat. These three features are almost invariably sufficient to distinguish between an intermittent pulse due to an extra-systole which fails to reach the wrist and an intermittent pulse due to partial heart-block. A polygraphic tracing or an electro-cardiogram will place the matter beyond all possibility of doubt. It may here be noted that it is necessary to exclude sinus irregularity, and also sino-auricular block, in cases of an unusually long pause in the radial pulse. The differential diagnosis between pulsus bigeminus,

pulsus trigeminus, and infrequency, including halving, of the pulse rate, due on the one hand to extra-systoles, and on the other to partial heart-block, can readily be made, as a rule, by means of palpation and auscultation.

It is sometimes very difficult, if not impossible, by palpation and auscultation alone, to diagnose extra-systoles, occurring frequently and at irregular intervals, especially if of auricular origin, from auricular fibrillation; but in such cases a sphygmographic tracing is almost invariably sufficient. It is also necessary to exclude auricular flutter when the response of the ventricle to auricular contraction is at irregular intervals (pp. 879, 880, and Fig. 96).

Prognosis.—The question of prognosis of extra-systoles is very important. Unfortunately the lay mind has come to attach an unnecessary significance to them. Furthermore, it is important that the medical practitioner should understand that extra-systoles constitute one of the most frequent causes of irregularity of the pulse, and that an extra-systole which fails to reach the wrist is the commonest cause of an "intermittent" pulse. *When extra-systoles are considered by themselves—that is, without reference to the conditions with which they may be associated*—there is so far no evidence for supposing that they are either indicative of an impaired heart or that they add to the gravity of any existing morbid condition. While it is true that extra-systoles may precede the occurrence of other forms of cardiac irregularity, such as the complete irregularity associated with auricular fibrillation, it should be borne in mind that these might have arisen independently. The prognosis, therefore, should be based entirely upon the causal or associated condition.

Treatment.—Our first duty is to reassure the patient; this may be done with absolute confidence. The etiology of extra-systole should be reviewed, the general health should receive attention, and if cardiac failure be present it should be treated on the lines laid down elsewhere. I have never found digitalis or quinidine of any value for the irregularity itself. Sedatives (see page 833) are frequently of benefit for the associated symptoms, especially when there is irritability of the nervous system or insomnia.

HEART-BLOCK

SINO-AURICULAR BLOCK

Sino-auricular block is a rare condition, in which the auricle fails to respond to the normal stimulus from the sino-auricular node, and pauses of the whole heart occur, giving rise to an intermittence of the pulse, or "dropped" beat. The length of the long pause is generally rather less than the duration of two normal cardiac cycles. Occasionally, alternate stimuli from the sinus fail to excite the auricles, and a slow heart rate results. The rate may double abruptly on exertion. Rarely successive stimuli from the sinus are blocked, resulting in long pauses of the heart and it may be a syncope or even Adams-Stokes syndrome. Sino-auricular block is sometimes induced by full doses of digitalis. The cause of the condition is not known, but in some cases it appears to be of vagal origin. Not infrequently it is associated with some degree of auriculo-ventricular block.

AURICULO-VENTRICULAR BLOCK

It has been noted that the stimulus for contraction is conveyed from fibre to fibre by means of a specialised function of the cardiac muscle-fibres called conductivity, and that the *a-c* interval in a polygraphic tracing is a measure of this function.

There are three degrees of depressed conductivity: (1) The stimulus from the auricle to the ventricle may be merely delayed—that is, there is merely a prolongation of the interval which separates the commencement of contraction of the auricle and that of the ventricle, each stimulus of the auricle reaching the ventricle, which duly responds. (2) The stimulus does not always reach the ventricle—in other words, the ventricle does not always respond to the stimulus from the auricle. The first two degrees are called “partial heart-block.” And (3) no impulses reach the ventricle from the auricle, so that the auricles and ventricles beat independently of each other; the former in response to stimuli received from the sinus, and at an approximate rate of 72 per minute; and the latter as the result of stimuli arising in the auriculo-ventricular junctional tissues between the site of the lesion

FIG. 35.—Simultaneous tracings of the jugular and radial pulses, from a case of myocardial degeneration. The *a-c* interval is more than $\frac{1}{4}$ th second.

and the division of the auriculo-ventricular bundle into two branches, at about 30 per minute, because this is the normal ventricular rate; this is called “complete heart-block,” “disassociation of the auriculo-ventricular rhythm,” “idio-ventricular rhythm,” or the “paroxysmal form of bradycardia.” Rarely complete heart-block is associated with auricular fibrillation or auricular flutter.

FIRST DEGREE OF DEPRESSED CONDUCTIVITY.—This grade of heart-block may give rise to irregularity of the pulse on account of variations in the length of the *a-c* interval. Some writers believe that contraction of the auricle produces a faint muffled sound, and that consequently when there is a slight delay between the auricular and ventricular contractions there may be a reduplication of the first sound, while if the delay be considerable, so that the contraction of the auricles falls in early diastole, there may be a reduplication of the second sound. It is also believed by some that in cases of mitral stenosis unaccompanied by auricular fibrillation a slight interval between the auriculo-systolic thrill and apex-beat, as well as between the auriculo-systolic murmur and first sound, is to be noted. In a polygraphic tracing, there is merely an increase in the *a-c* interval, it exceeding $\frac{1}{4}$ th of a second (Fig. 35).

SECOND DEGREE OF DEPRESSED CONDUCTIVITY.—In this condition what are called "dropped beats" occur (Fig. 36). These may be only occasional, or they may be more frequent. Or each third or fourth impulse may fail to reach the ventricle; in the former case the ventricular beats are grouped

FIG. 36. Simultaneous tracings of the jugular and radial pulses, from a case of aortic and mitral disease, showing partial heart-block. There are three blocked auricular impulses. The a - c interval is $\frac{1}{6}$ th second.

in twos (Fig. 28), and in the latter they are grouped in threes, and in this way a bigeminal or trigeminal pulse results. Or every other impulse may fail to reach the ventricle, giving rise to halving of the ventricular rate, the condition being spoken of as 2 : 1 rhythm (Fig. 37); or only each third or fourth auricular impulse may be transmitted to the ventricle, resulting in 3 : 1 or 4 : 1 heart-block. In some cases certain ratios alternate.

It might naturally be supposed that the length of the prolonged pause

FIG. 37.— Simultaneous tracings of the jugular and radial pulses, showing continuous 2 : 1 auriculo-ventricular block. The pulse-rate is 42 per minute.

during a dropped beat would be equal to two regular pulse-beats; such, however, is usually not the case for the following reason. There are variations in the A - V s interval in association with dropped beats, there being a progressive increase of the A - V s interval preceding and a progressive shortening of the interval following each dropped beat; the former is due to the increasing difficulty the impulses from the auricle have in reaching the ventricle, and the latter to the rest which the ventricle has experienced during the pause. The result of the progressive increase of the A - V s interval prior to, and of the progressive shortening of the A s to V s interval after, the dropped beat is that the long pause becomes shortened.

When, however, there are no variations in the A_s-V_s interval in association with a dropped beat, the length of the prolonged pause is equal to two regular pulse-beats.

2 : 1 heart-block gives rise to infrequency of the pulse-rate, the rhythm being regular. This grade of heart-block is sometimes continuous, but usually the ventricle responds from time to time to successive stimuli received from the auricle, the pulse-rate, therefore, being usually above 36 per minute.

On analysis of a polygraphic tracing it will be found that the a wave is present at uniform intervals, and is of more frequent occurrence than the c or v waves—it may be even twice, three, or more times as frequent, according to the degree of block; but, unlike complete heart-block, each c wave is preceded by an a wave (Figs. 36 to 38).

COMPLETE HEART-BLOCK.—Here the pulse-rate is slow, usually not more than 36, and not infrequently between 20 and 30 per minute, though some cases have been recorded in which the rate has been up to 60 or more beats per minute; it is little influenced by physical exertion, emotion, or pyrexia, or, as a rule, by atropine. The beats are usually full and strong, and, as a

FIG. 38.— Simultaneous tracings of the jugular and radial pulses, showing partial heart-block. Note the progressive increase in the a - c interval of three successive rhythmic beats.

rule, the rhythm is regular, the pulse being irregular, however, when extrasystoles are present. In a tracing of the radial artery small waves occurring at regular intervals on the descending limb of the pulse-beat, probably due to auricular systole, may sometimes be noted. The systolic blood-pressure is generally high, and during the long pause there is a considerable drop in pressure; the mean blood-pressure is low. There is usually evidence of hypertrophy of the left ventricle. On inspection of the neck, regular pulsations in the jugular veins, at considerably more frequent intervals than, and having a constantly varying time-relation to, those of the radial and carotid arteries and the apex-beat, due to auricular systole, may sometimes be noted; and in some instances a large pulsation in the jugular vein is seen from time to time when the auricular and ventricular contractions happen to coincide. On auscultation a first and second sound are found accompanying each contraction of the ventricle, and, in the opinion of some, faint muffled sounds may occasionally be heard during the long pauses, due to the contractions of the auricle. Some writers, too, have noted an accentuation of the first sound, synchronous with the large pulsation in the jugular vein, when the auricular and ventricular contractions coincide. In the case of a lesion of either main division of the auriculo-ventricular bundle, the gallop rhythm may be audible, due to asynchronism of the two ventricles.

If a polygraphic tracing be analysed (Fig. 39), the disassociation of the auricular and ventricular rhythms is manifest. The *a* waves occur at regular intervals, and are more numerous than the *c* or *v* waves, and the time-relation of the *a* and *c* waves is a constantly varying one—the *a* waves at one time preceding, at another following, and at other times again coinciding with the *c* waves. When an *a* wave falls during the limits of ventricular systole its amplitude is increased. Extra-systoles may be present.

✓ **Ætiology.**—Heart-block is more common in males than in females. Most of the cases fall within two groups—(1) Patients, usually young adults, who have previously suffered from a rheumatic infection of the heart; and (2) patients, usually elderly people, who are suffering from chronic interstitial myocarditis. In the former group the block is almost always of slight degree; but in these cases the higher degrees of heart-block are sometimes induced by full doses of one of the digitalis series of drugs. In the latter group there is a past history of syphilis in a small proportion of cases. The milder grades of heart-block may also be found in patients suffering from acute infective diseases, such as acute rheumatism, influenza, diphtheria, and pneumonia; the condition, however, is usually temporary in these diseases.

FIG. 39.—Simultaneous tracings of the jugular and radial pulses, from a woman aged 25, with severe heart failure, showing complete auriculo-ventricular block. The auricular rate is 88, and the ventricular rate 30, per minute.

Rarely complete heart-block is congenital, and may be due to interruption of the auriculo-ventricular bundle by an aperture in the inter-ventricular septum.

Pathology. The commonest pathological findings in cases of heart-block are atheroma of the coronary arteries and fibrosis of the myocardium. Usually, involvement of the auriculo-ventricular junctional tissues is part of a widespread myocardial fibrosis, but occasionally the special artery to the bundle, a branch of the right coronary artery, is narrowed or occluded, and the lesion is more limited. Syphilitic lesions occur, but are not common, and even in syphilitic patients, atheroma of the coronary arteries may be the cause of heart-block. Acute inflammatory changes are found when heart-block occurs during an acute infective disease, such as diphtheria. Cases have been recorded, however, in which no lesion could be demonstrated in the auriculo-ventricular junctional tissues, and the vagus has been held responsible.

Symptoms.—Patients suffering from heart-block may complain of symptoms due to the associated cardiac lesions—whether valvular or myocardial—which are almost invariably present, as well as of those due to the block itself; when, however, the valves and myocardium are normal, there may be a complete absence of subjective symptoms.

The symptoms of valvular and myocardial disease will be dealt with later; the commonest of these are dyspnoea, palpitation, fatigue, and præcordial pain on exertion.

With regard to the symptoms due to the block itself, reference has already been made to the pulse, the blood-pressure, the auscultatory phenomena, and the polygraphic records. In most cases symptoms due to the ventricular bradycardia are present. In the severe grades of partial heart-block and in complete heart-block there may be marked weakness and fatigue; and, owing to temporary anæmia of the brain, brief attacks of faintness, giddiness, or even temporary loss of consciousness. Not infrequently there are temporary periods of excessive slowing, or cessation of ventricular systole for prolonged intervals. Cheyne-Stokes respiration may be present, and the Adams-Stokes syndrome may occur.

ADAMS-STOKES SYNDROME.—Adams-Stokes syndrome is characterised by attacks of loss of consciousness, which may be momentary, and, it may be, also by epileptiform convulsions, associated with marked infrequency of the ventricular rate. The patient, as a rule, has no knowledge of an impending attack. During the seizure there may be marked pallor or cyanosis, and deep and even stertorous breathing. Usually the convulsions are confined to the face and the upper limbs, the tongue is not bitten, and urine is not passed involuntarily. There may be repeated seizures. Adams-Stokes syndrome may occur in one of the following conditions: (1) Suddenly developed transient complete auriculo-ventricular block. Several cases of this kind have been reported. The conduction of the stimulus for contraction along the auriculo-ventricular junctional tissues is normal except that there is a liability to transient interruptions. (2) Partial heart-block, in which there occurs either an intermittent period of complete heart-block, resulting in a temporary standstill of the ventricles; or, rarely, merely a temporary increase in the grade of the partial heart-block, resulting in a temporary increase in the degree of the bradycardia. (3) Complete heart-block, in which the condition has become permanently established, especially if the ventricular rate is below 30 per minute. In these cases pauses of unusual length, due to temporary standstill of the ventricles, the result of diminished irritability of the ventricles, may occur. (4) It may very rarely be met with in marked bradycardia, in such conditions as meningitis, increased intracranial pressure, during convalescence from acute infective diseases, especially diphtheria and influenza, and possibly in fatty degeneration. Taking cases as a whole, Adams-Stokes syndrome is most commonly met with in patients with a severe grade of partial heart-block in whom complete block is developing. When complete heart-block has become permanently established, the ventricles apparently tend to become accustomed to the condition, and the pauses of unusual length referred to are not so likely to occur.

Diagnosis.—Diminished conductivity and the various grades of auriculo-ventricular heart-block are readily recognised by means of the polygraph or electro-cardiograph, since these instruments afford separate records of the movements of both the upper and lower chambers of the heart. The first grade can only be recognised by means of either of these instruments, and a lesion of either main division of the auriculo-ventricular bundle and intra-ventricular block by means of the electro-cardiograph. Fortunately, however, they are not necessary for the recognition of most of the other cases—

palpation and auscultation furnishing all the evidence required. As an example of this may be mentioned the differential diagnosis between occasional dropped beats, pulsus bigeminus, and pulsus trigeminus, due on the one hand to extra-systoles and on the other to partial heart-block; this has already been dealt with. It is necessary to remember that sometimes sinus irregularity, and also sino-auricular block, may closely simulate occasional dropped beats due to partial heart-block.

The higher grades of heart-block give rise to infrequency of the pulse-rate. When the ventricular rate suddenly falls to half its former rate, in all probability the case is one of 2:1 heart-block. 2:1 heart-block must be distinguished from the condition in which an extra-systole occurs after each normal beat and fails to reach the wrist on each occasion. This can be done in the same way as in the case of a less severe grade of heart-block. It is sometimes difficult to distinguish between partial and complete heart-block without the aid of the polygraph or electro-cardiograph. Most cases with a ventricular rate of 36 or under, however, are cases of complete heart-block. Also the presence of more rapid pulsations in the jugular veins, the presence of small waves occurring at regular intervals on the descending limb of a sphygmogram, and auscultatory phenomena afford help in differential diagnosis. A polygraphic or electro-cardiographic tracing may be taken to determine disassociation of the auricular and ventricular rhythms.

Adams-Stokes syndrome is easily recognised; marked infrequency of the ventricular-rate, rapid pulsations in the jugular veins, and the symptoms already described furnish a characteristic clinical picture.

Prognosis.—*The occurrence of partial heart-block during the course of an acute infective disease is a sign, and may be the only sign, of myocardial involvement.* Persistent heart-block of mild degree also is indicative of myocardial damage. With regard to persistent heart-block of severe degree, there are two questions of importance in considering the prognosis, namely—(1) Whether there be involvement of the heart muscle as a whole, and whether this involvement be progressive; and (2) is the patient subject to syncopal attacks, and, if so, what is their frequency? When there are no symptoms of heart failure, and when also the patient does not suffer from syncopal attacks, the span of life may be prolonged for many years, and he may be able to live a fairly active life without inconvenience. But when indications of cardiac failure are present, and especially if these be progressive, and when the patient is subject to recurrent syncopal attacks, especially if severe and frequent, life is always in danger; and, apart from the risk of a fatal termination during an attack, death may occur with the usual clinical picture of cardiac failure. A few syphilitic cases have been recorded in which energetic anti-syphilitic treatment appears occasionally to have been rewarded with recovery.

Treatment.—When there is reason to suspect that syphilis is the cause, appropriate and energetic anti-syphilitic treatment should be employed. When heart-block occurs during the course of acute infective diseases, rest in bed is indicated, and the cause, such as rheumatism, should be adequately treated. Persistent heart-block of mild degree requires no treatment in itself. But as there is usually valvular or myocardial disease or both, it is of great importance that the patient should live strictly within the limits of the heart's strength, all the more so in cases of persistent heart-block of severe degree.

If the patient be subject to fits, he should be warned to avoid anything known to predispose to the attacks, and, as far as possible, he should be protected from the risks of falling. Digitalis is contra-indicated in partial heart-block. It may be tried in complete heart-block in which there is dropsy or some other indication for its use.

ADAMS-STOKES SYNDROME.—The foregoing therapeutic measures may be indicated. Anti-syphilitic treatment is indicated in Adams-Stokes syndrome due to auriculo-ventricular block when this is the result of gummatous infiltration. Potassium iodide by its depressing effect on the ventricular muscle, may even aggravate the complaint when the cause is other than syphilis. Thyroid appears to be sometimes of value and may even be completely effective. Atropine, administered between the attacks in order to prevent their recurrence, is indicated in cases of partial heart-block in which there is vagal over-activity. Digitalis is contra-indicated in partial heart-block. It may be of value in complete heart-block. Caffeine and theobromine are of no clinical value. Of reported cases, the nitrites were found to be only of doubtful value in one case. Adrenaline is of value in the great majority of cases. It is not often effective in preventing the recurrence of the attacks. When employed for this purpose it may be administered either subcutaneously or intramuscularly, in a dosage of from 5 to 10 minims of 1 : 1000 solution thrice daily. It is, however, the only potent therapeutic measure at our disposal during an actual attack. It is necessary to point out that when—as in the vast majority of cases—the attack is due to a temporary standstill of the ventricles, with consequent temporary cessation of the circulation, intravenous or intracardiac injection is necessary, because the beneficial effect of the drug is due to its action in stimulating the sympathetic nerve endings in the heart muscle. The dose should be 0.5 to 1 c.c. of 1 : 1000 solution. In the rare cases in which the attacks are due to merely a temporary increase in the grade of an existing partial heart-block, the drug may be effective even if given subcutaneously or intramuscularly. Ephedrine has recently been employed as a substitute for adrenaline. It differs from adrenaline in that its effect persists for several hours; and, moreover, it has the great advantage of being effective when administered orally. A highly successful case treated by this drug has been reported, and therefore further investigation of it is advisable. Barium chloride, given by the mouth, should invariably be tried for the prevention of the recurrence of the attacks in cases of Adams-Stokes syndrome due to auriculo-ventricular block. If ineffective alone the drug should be employed with adrenaline, the latter administered either hypodermically or intramuscularly. The following is recommended: That barium chloride be administered, at first in doses of $\frac{1}{2}$ gr. thrice daily. This dosage should, if necessary, be cautiously increased—stopping short of toxic symptoms—to 1 gr. thrice daily. With regard to adrenaline, 0.5 c.c. to 1 c.c. of 1 : 1000 solution should be given thrice daily until after the attacks have ceased for some time. The dosage of adrenaline should then be gradually diminished until the drug is omitted altogether. Still later, the dosage of barium should be gradually reduced to the minimal dose found necessary to prevent the recurrence of the attacks.

CONGENITAL AURICULO-VENTRICULAR BLOCK.—A number of cases of congenital auriculo-ventricular block, usually accompanied by some other

lesion, have been described during the last 20 years or so, but, owing to the absence of polygraphic or electro-cardiographic examination, some of them were very doubtful. In most cases the pulse was over 50 per minute, and only rarely was there the Adams-Stokes syndrome. The condition is usually ascribed to a lesion of the auriculo-ventricular bundle, and among the theories put forward as to its nature are (1) that it consists in a severance of the continuity of a bundle by an intraventricular communication, (2) that it is due to malformation, and (3) that it is inflammatory in origin.

BUNDLE-BRANCH BLOCK

A temporary or permanent lesion of either the right or left main branch of the auriculo-ventricular bundle is uncommon. The left appears to be much more frequently affected than the right (new nomenclature). The ætiology and pathology are similar to those of auriculo-ventricular block. Sometimes auriculo-ventricular block, and less frequently auricular fibrillation (Fig. 88), may coexist with a lesion of either main branch. Reduplication of the first sound is not infrequently to be observed. The condition can be recognised by means of the electro-cardiograph alone (see pp. 996, 997). When the condition is permanent, the prognosis is usually very unfavourable.

PARTIAL BUNDLE-BRANCH BLOCK (see pp. 997-998)

INTRAVENTRICULAR (ARBORISATION) BLOCK

In this condition there is diminished conductivity of the sub-endothelial arborisations of the auriculo-ventricular bundle, and also the stimulus for contraction does not reach the various portions of the ventricular muscle in normal sequence. It is believed by some that the condition may be recognised by means of the electro-cardiograph (see page 998). The prognosis is almost always grave.

PULSUS ALTERNANS

Definition.—By pulsus alternans is meant a condition of the pulse in which, while the rhythm is perfectly regular, a large beat and a small beat alternate. It is probably indicative of depressed contractility.

In the most typical cases of pulsus alternans, stimulation and contraction of the sinus, the auricles, and the ventricles occur in the order named, the ventricles contracting only in response to stimuli received from the auricles, and ventricular systole following the auricular systole at the normal interval (Fig. 40). Sometimes, however, pulsus alternans is associated with conditions in which the mechanism of the cardiac action is abnormal, such as auricular flutter (Fig. 41), or paroxysms of auricular extra-systoles. The condition may be continuous, or it may be only observed on an increase of the pulse-rate, such as follows exercise, or only during a few cycles immediately following an extra-systole.

Ætiology.—Excluding those cases that occur in association with an abnormal cardiac action, such as auricular flutter, in the great majority of cases patients showing pulsus alternans are past middle age, and are the subjects of hypertension, cardiac hypertrophy, or myocardial degeneration; the

condition, however, is sometimes found in younger people with post-rheumatic valvular disease, and occasionally it has been noted in pneumonia and other acute illnesses.

Symptoms.—The pulsus alternans in itself causes no subjective symptoms. When associated with myocardial disease, evidences of cardiac failure are

FIG. 40.—Simultaneous tracings of the jugular and radial pulses, showing continuous pulsus alternans, in which stimulation and contraction of the sinus, auricles and ventricles occur in the order named.

almost invariably present. Sometimes the small beats are so feeble that no waves are transmitted to the wrist; the condition may, therefore, be a cause of infrequency of the pulse.

Diagnosis.—Gross alternation of the pulse can usually be recognised by the finger. Lesser grades can be readily detected by the sphygmomanometer. The pressure in the armlet is raised, until the pulse below it disappears, and then lowered very gradually. The larger beats reappear at a

FIG. 41.—Simultaneous tracings of the jugular and radial pulses, showing pulsus alternans associated with an attack of auricular flutter, in which the ratio between the auricular and ventricular rate is continuously 2 : 1.

higher pressure than the smaller beats, so that just below systolic level the pulse rate is halved. The auscultatory method is the best method. In extreme cases the difference in pressure between the large and small beats may be 20 to 30 mm., but usually it is only 1 to 5 mm. A radial tracing is valuable in distinguishing pulsus alternans from pulsus bigeminus due to extra-systoles. In the case of the former the beats are evenly spaced, but in the latter the pause following the small beat is longer than that following the large beat.

Prognosis.—When pulsus alternans occurs apart from a disordered cardiac mechanism, it is an indication of extreme exhaustion of the heart muscle; when the condition lasts only for a few cycles, this exhaustion may be only temporary, but even in these cases the prognosis should be guarded; when it is continuous, death may follow within a few months, or at most in a few years. When the condition is associated with tachycardia, it does not appear to have any serious significance in itself.

Treatment.—As pulsus alternans is usually a sign of great exhaustion of the heart muscle, complete and long-continued rest, both physical and mental, is urgently needed. ✓

AURICULAR FIBRILLATION

It is of the utmost practical importance that auricular fibrillation should be recognised, owing to its bearing on the diagnosis, prognosis and treatment of cardiac affections. It is a specific clinical condition which can be recognised with certainty. It is characterised in the vast majority of cases by complete irregularity of the arterial pulse, and also by absence of all signs of the normal contraction of the auricles. It accounts for approximately 50 per cent. of all cases of persistent irregularity of the heart, and it is found in from 60 to 70 per cent. of all cases of serious cardiac failure with dropsy. The condition has been known variously as “delirium cordis,” “pulsus irregularis,” “pulsus irregularis perpetuus,” and the “mitral” pulse.

Definition.—By auricular fibrillation is meant a condition in which co-ordinate contraction in the auricle is replaced by inco-ordinate contraction; the individual fibres, instead of contracting in an orderly and simultaneous manner, doing so rapidly and independently of each other, with the result that *systole of the chamber as a whole never takes place*. When auricular fibrillation has once set in, in the great majority of cases it persists. But, instead of this, it may be paroxysmal. Many cases of paroxysmal tachycardia are due to paroxysmal auricular fibrillation. The tendency to occurrence increases, however, until finally the condition usually becomes persistent.

EFFECT OF AURICULAR FIBRILLATION ON THE HEART.—The effect of auricular fibrillation on the cardiac action is mainly threefold: (1) The forcible contraction of the auricles driving the blood through the open auriculo-ventricular valves into the ventricles during the latter part of ventricular diastole is lost. This results in the ventricle being less filled. (2) Instead of the ventricle receiving stimuli from the auricle at regular intervals, it receives them at completely irregular intervals. (3) The impulses which escape from the auricle are numerous, and in the vast majority of cases the junctional tissue is able to conduct too many to the ventricle, resulting in an increase in the ventricular rate. The result of these three factors combined is that some of the ventricular contractions are so feeble as to fail to open the aortic valves, and the pulse is diminished in volume and its rhythm is irregularly irregular. In my opinion, the third factor is the most important. The condition usually has a considerable effect on the heart's efficiency.

Ætiology.—The majority of cases of auricular fibrillation fall within two groups—(1) those with a history of rheumatism, and (2) patients suffering

from myocardial degeneration. In the case of the former the condition occurs more commonly in early adult life, and the patients frequently have valvular disease—*much more often mitral than aortic disease, and more especially mitral stenosis*. In the second group of cases the condition is more common after middle age. Auricular fibrillation has been also found occasionally in acute infective diseases, such as pneumonia, infective endocarditis, and diphtheria, in thyrotoxic conditions (see pp. 963–964), and in the terminal stages of various exhausting diseases. Its onset can now and again be traced to bodily effort, especially in the middle-aged or elderly, and rarely to the administration of full doses of digitalis.

Pathology.—Auricular fibrillation is, in the vast majority of cases, indicative of some myocardial change.

It was observed by Mackenzie that, in cases of complete irregularity of the pulse, the pre-existing auricular wave in the phlebogram had disappeared. From this he inferred first, that the auricles were paralysed and, later, instead of this, that nodal rhythm was present. Some time afterwards Rothberger and Winterberg and Lewis attributed the absence of auricular contractions to auricular fibrillation—a condition which had been produced experimentally in animals.

The exact mechanism of auricular fibrillation has been further elucidated by Lewis and his co-workers, and it is now generally accepted that a *circus movement* is responsible. Mines and Garrey had demonstrated that in a circular ring of muscle, under certain conditions, a wave of contraction can be made to circulate continuously. This is only possible if the crest of the circulating wave encounters muscle which is responsive, *i.e.* which has recovered from the refractory state that immediately follows contraction. Thus, the refractory period at a given point on the circuit must be less than the time taken by the wave to make a full circuit. If we consider a wave of contraction circulating in such a simple muscular ring, at any given moment, the crest of the wave has in its wake a zone of muscle which is refractory, and between the tail of the refractory zone and the crest of the wave is a zone of muscle which is responsive, known as the gap. The length of this gap is influenced by three factors, namely: (1) The length of the circular path; (2) the rate at which the wave circulates; and (3) the refractory period of the muscle. Lengthening of the path, slowing of the conduction rate, and shortening of the refractory period tend to increase the gap; while shortening of the path, increase of the conduction rate, and lengthening of the refractory period tend to decrease or abolish the gap.

It has been shown that in both auricular fibrillation and auricular flutter a *circus movement* is present in the auricles, which no longer respond to the regular stimuli from the sino-auricular node. In auricular flutter the pathway of the main circulating wave probably encircles the orifices of the two venæ cavæ. The wave circulates at a rate of 180 to 350 per minute, and constantly traverses the same path. In auricular fibrillation the circulating wave is faster, being between 400 and 600 per minute, and the path is shorter, more sinuous and variable. The gap is very short, so that the crest and the wake of the circulating wave are almost fused, and the crest is advancing through irregular channels. In both flutter and fibrillation the auricular muscle is responding to stimuli from a central circulating wave, from which

offshoots or subsidiary waves pass in all directions towards the periphery. Intermediate between pure flutter and fibrillation is a condition termed impure flutter, in which the rate of the circulating wave is 350 to 400, and the path traversed is not absolutely constant, as in the case of pure flutter.

Prolongation of the refractory period in auricular fibrillation and in auricular flutter will help to close the gap between the crest of the oncoming wave and its receding wake, since this gap is necessary for the maintenance of the circulating wave, whether in flutter or fibrillation.

Symptoms.—Patients with auricular fibrillation very frequently complain of fluttering in the præcordium, or of irregular action of the heart, or of both, possibly only on exertion. Apart from this, there is occasionally an absence of subjective symptoms. But, when the ventricular rate is much above the normal, symptoms, as a rule, are present, and these are the same as those of cardiac failure from other causes, such as shortness of breath, a sense of exhaustion, cyanosis and dropsy. It would appear, however, that the subjects of auricular fibrillation rarely suffer also from typical attacks of angina pectoris. When the ventricular rate is very slow, the Adams-Stokes syndrome may be present.

The degree of cardiac failure which arises as a result of auricular fibrillation may be slight or very severe. It depends upon (a) the ventricular

FIG. 42.—Tracing of the radial pulse, from a case of auricular fibrillation, showing complete irregularity of the pulse.

rate, and (b) the degree of inherent muscle defect. As a rule, the onset of symptoms is gradual, but may ensue rapidly, and the patient may become very ill within a few hours. Similarly, the cessation of auricular fibrillation may be accompanied by an equally rapid improvement in the patient's condition.

There is a wide variation in the ventricular rate, according as the pathway for impulses to the ventricle is free or interfered with, this ranging from 140 or even 180 to 40, or, very rarely, even 30 per minute in complete auriculo-ventricular heart-block, the average rate being between 90 and 140. The rate of the radial pulse does not necessarily represent the ventricular rate, for many beats of the heart may not be transmitted to the wrist, especially when the ventricle is beating rapidly; the ventricular rate, therefore, should be counted at the apex, by auscultation. Apart from the very rare cases of complete auriculo-ventricular block, when the pulse is regular, the character of the pulse is important. It is irregular, the irregularity being continuous in the great majority of cases, in this respect differing from most other types of cardiac irregularity. A feature of even greater importance is the fact that the irregularity is complete; the rhythm is irregularly irregular (Fig. 42). In a sphygmogram it will be found that two beats of the same length or amplitude rarely follow each other. There is often no relation also between

the length of a pause and the amplitude of the beat which follows it—i.e. a short pause may be followed by a strong beat, and a long pause by a weak beat. The more rapid the pulse the greater the irregularity. In contrast, the sinus and extra-systole irregularity increases the quickening of pulse-rate. There may be superadded ventricular extra-systoles, occurring either isolated at irregular intervals, or, as is more usually the case, occurring regularly after each normal ventricular beat. In the latter event, there is either coupling of the beats (Fig. 43), or the premature contraction may be so feeble

FIG. 43.—Tracing of the apex-beat, from a case of auricular fibrillation, fully under the influence of digitalis, showing coupled beats.

that no wave reaches the wrist, in which case the pulse-rate is halved. When the ventricular rate is slow, or very rapid, the irregularity may be only slight, and we may have to adopt careful measurements of the sphygmogram to detect it.

In cases of mitral stenosis in which a presystolic bruit, *due to auricular systole*, is present, this disappears with the onset of auricular fibrillation; while if a diastolic bruit be present, it persists. The jugular veins may be so distended that there is no visible pulsation in them. When pulsation is

FIG. 44.—Simultaneous tracings of the jugular and radial pulses, from a case of auricular fibrillation, showing multiple undulations (marked *Fib.*) in the phlebogram, caused by the fibrillating auricle.

visible, however, it is of the positive type, only one wave being visible, this occurring during ventricular systole. In a tracing of the jugular vein, apart from the very rare cases of complete auriculo-ventricular block, when the rhythm is regular, the rhythm is completely irregular. There is an absence of the *a* wave. There may be the ventricular form of venous pulse. In cases in which there is infrequent cardiac action, multiple undulations, caused by the fibrillating auricle, may be present during diastole (Fig. 44). There is also an absence of the normal *a* wave in a cardiogram and in a tracing of the liver pulse.

Diagnosis.—Auricular fibrillation can be diagnosed with absolute certainty on electro-cardiographic examination; or when complete irregularity of the arterial pulse, the ventricular form of venous pulse, and multiple undulations in the jugular pulse are present, together with an absence of all signs of an auricular wave in a tracing of the apex-beat and of the liver pulse. We may be certain that this condition is present when there is complete irregularity of the pulse in conjunction with the ventricular form of venous pulse. Indeed, *we may be reasonably sure of the existence of auricular fibrillation from the mere presence of complete irregularity of the pulse.* It is possible to determine complete irregularity of the pulse in a large proportion of cases by palpation and auscultation alone. When, however, the ventricular rate is slow, or very rapid, the irregularity may be only slight, and it may be necessary to adopt careful measurements of the sphygmogram to detect it. It is necessary to exclude irregular action of the heart due to extra-systoles (p. 861), or to auricular flutter (p. 879).

Prognosis.—Auricular fibrillation is in the vast majority of cases indicative of some myocardial change. Furthermore, the condition usually has an effect on the functional efficiency of the organ. Put briefly, the prognosis of auricular fibrillation depends upon the capacity of the heart to carry on its work under the new rate and rhythm, and this in turn depends upon the integrity of the cardiac muscle and the ventricular rate. If the integrity of the cardiac muscle be relatively good there may be for years little or no indication of cardiac failure. In the great majority of cases, however, this is not the case, and so heart failure, usually of considerable degree, results, especially when the ventricular rate is rapid and the heart is dilated. A persistent ventricular rate of 120 or over is usually of serious omen. Occasionally, with the inception of auricular fibrillation, grave cardiac failure may supervene with surprising rapidity, and death may follow within a few weeks, or even within a briefer period.

In endeavouring to form a prognosis, a point of the utmost importance is to ascertain how the heart responds to treatment. In this connection, digitalis therapy and quinidine therapy have been fully dealt with on pages 835-840. Another point of the utmost importance is to ascertain how far the patient is able to modify his life so as to bring it within the limits of the heart's strength. As has been pointed out, paroxysmal auricular fibrillation has a tendency to become more frequent, until ultimately the condition becomes persistent. Auricular fibrillation associated with thyrotoxicosis is dealt with on p. 964.

Treatment.—The ætiology should be reviewed, with the object of treating the underlying cause, and the various therapeutic measures applicable to any form of cardiac disorder should be considered in detail. Apart from these, treatment of persistent auricular fibrillation resolves itself into the consideration of the employment of digitalis or of quinidine. The ultimate object of the employment of either of these drugs is the same, namely, to regain the degree of cardiac efficiency which existed prior to the onset of the abnormal rhythm. This in the main depends upon the restoration of the pre-existing ventricular rate. The fundamental functions of digitalis and of quinidine differ. The primary object of administering digitalis in auricular fibrillation accompanied by a rapid ventricular rate is to reduce and control the ventricular rate within normal limits. The drug has no effect upon the

auricular fibrillation itself. The primary object of administering quinidine, on the other hand, is to arrest the auricular fibrillation—in other words, to restore the normal rhythm, and any beneficial effect of the drug is simply due to this. The indications for, and the methods of administration of, these drugs have been fully discussed on pages 835–840.

In considering which drug should be employed, the degree of response to digitalis is of important consideration, a manifestation on the part of the patient of a particular intolerance for the former being a special indication for the administration of quinidine. It should, however, be remembered that the greater the degree of response to rest and digitalis medication the more likelihood there is of greater benefit following the administration of quinidine. Another special indication for quinidine is the occurrence of cardiac failure coincidently with the onset of the abnormal rhythm. The absence of indications of cardiac failure does not necessarily mean that this drug should not be tried, as cardiac failure may supervene later on. Other considerations are the risk—even amounting to a possible fatal issue—attending the administration of the drug, the degree of probability of restoration of the normal rhythm, the probable degree of success resulting from this, and the degree of probability of relapse. Cases for the administration of the drug should be selected with the utmost care, and in selecting such cases we are justified in taking a comparatively small risk, while in doubtful cases we should clearly put the pros and cons of this method of treatment to the patient or his friends. Lastly, it should be remembered that if quinidine fails, digitalis medication is still open to us. In conclusion, since the introduction of quinidine in the treatment of auricular fibrillation, its use is undoubtedly becoming more restricted, digitalis being regarded as the routine method of treatment, and quinidine being reserved for special cases.

The treatment of paroxysmal auricular fibrillation is that of paroxysmal tachycardia.

The treatment of auricular fibrillation associated with thyrotoxicosis is discussed on p. 964.

AURICULAR FLUTTER

Auricular flutter is a specific clinical condition, not uncommon, in which a marked acceleration of the rhythmic co-ordinate contraction of the auricles occurs.

The rate of the contractions of the auricle may range from 180 to 380, perhaps being usually between 240 and 300 per minute. The ventricular rate varies considerably in different cases, this depending upon the auricular rate and the ability of the auriculo-ventricular junctional tissues to receive and transmit the impulse sent by the auricle. Rarely the ventricle responds to each auricular contraction, resulting in 1 : 1 rhythm. In the vast majority of cases, however, this is not so, partial heart-block being present. In these cases there is usually a constant and uniform ratio between the auricular and ventricular rate, this varying from 5 : 1 to 2 : 1. It would appear that the order of frequency is 2 : 1, 4 : 1, and 3 : 1. In some cases the response of the ventricle to auricular contraction is at irregular intervals, instead of

being in definite ratio, this giving rise to irregularity of the pulse rhythm. Rarely complete auriculo-ventricular block is present.

The commencement and termination of auricular flutter are sudden and abrupt. The condition may be paroxysmal or persistent. In the case of the former, it may be succeeded by the normal rhythm, or in many instances followed by auricular fibrillation, the latter occurring either during the administration of digitalis or apart from the use of the drug. When once a patient has suffered from an attack of auricular flutter, there is a tendency to its recurrence from time to time. There may be alternation of auricular flutter, the normal rhythm and auricular fibrillation, the change taking place with the greatest abruptness and suddenness, and occurring from day to day or even for a few moments. Either auricular flutter or auricular fibrillation may ultimately become permanently established. In persistent auricular flutter, the ventricular rate may diminish as the result of the occurrence of partial heart-block, and this may take place during the administration of digitalis or apart from the use of this drug.

The commencement and termination of auricular flutter are sudden and abrupt. The duration of the condition varies in different individuals, as well as in different paroxysms occurring in the same individual. Auricular flutter may appear for only a few moments and may never return; or it may last for hours, days, weeks, months, or even for years, recurring at intervals. It may be succeeded by the normal rhythm, or in many instances followed by auricular fibrillation; I have seen the latter occur during the administration of digitalis, but it may also occur apart from the use of the drug. There may be alternation of auricular flutter, the normal rhythm, and auricular fibrillation, the change taking place with the greatest abruptness and suddenness, and occurring from day to day or even every few moments, one or other condition ultimately becoming permanently established. When once a patient has suffered from an attack of auricular flutter, there is a tendency to its recurrence from time to time. Sometimes auricular flutter may persist, but, as the result of the occurrence of partial heart-block, the ventricular rate may diminish, and this may take place during the administration of digitalis or apart from the use of this drug.

EFFECT OF AURICULAR FLUTTER ON THE HEART.—The effect of auricular flutter on the heart depends upon the ventricular rate and the integrity of the myocardium. When the ventricular rate is rapid and the myocardium is considerably damaged, the condition produces a marked effect upon cardiac efficiency, frequently resulting in cardiac dilatation, dropsy and other indications of heart failure.

Ætiology.—The ætiology of auricular flutter is the same as that of auricular fibrillation (see pp. 871–872), except that it would appear that heart disease due to rheumatism and also thyrotoxicosis are relatively somewhat less frequent.

Pathology.—See pp. 872–873.

Symptoms.—The symptoms of auricular flutter depend upon the ventricular rate, the duration of the condition and the degree of integrity of the myocardium.

In the rare cases in which there is an absence of a material degree of tachycardia, very frequently the patient is unconscious of the action of the heart, and there may be only slight, if any, limitation of the field of cardiac

response. In those cases in which there is at least a material degree of tachycardia, in some the patient is able to recognise the onset of the condition. After the onset, he is usually conscious of the tachycardia, and generally complains of a fluttering sensation in the chest or, less frequently, of palpitation, and occasionally also of a sensation of pulsation in the neck. After some time, in the great majority of cases, the ordinary indications of cardiac failure supervene; or, if these were present before the onset of auricular flutter, they increase in severity, until ultimately indications of severe, or even extreme, failure, may appear. When there is marked tachycardia, the symptoms are similar to those of paroxysmal tachycardia (see pp. 883-884).

The rate and rhythm of the arterial pulse vary greatly in different cases and, it may be, at different times in the same case. If the ventricle responds to each auricular contraction, the ventricular rate is exceedingly rapid, and graphic methods are usually necessary to determine it. In the vast majority of cases, however, partial heart-block is present, and as 2:1 rhythm is the most usual, a ventricular rate of 120 to 150 is frequently found. In other cases of partial heart-block, the ventricular rate may not be much increased, and, indeed, there may be even bradycardia, as in 4:1, or more partial heart-block, as well as in complete heart-block. When there is a constant and uniform ratio between the auricular and ventricular rates, the rhythm of the arterial pulse is regular; in these cases, however, if the ventricular rate be above 150, *pulsus alternans* may be present. When, as is not infrequently the case, the response of the ventricle to auricular contraction is at irregular intervals, there is irregularity of the pulse rhythm; indeed, in some of these cases the sphygmogram may resemble that from a case of auricular fibrillation, detailed measurements being necessary for the purpose of differential diagnosis. An irregular pulse often becomes regular and more rapid as the result of exertion, due to the occurrence of 2:1 rhythm. On inspection of the neck, the jugular veins may be distended, and no pulsation visible; or very rapid movements may be evident.

A tracing of the jugular pulse differs in outline according to whether the ventricle responds to each auricular contraction, or to the degree of heart-block which may be present. In the former case there is usually a single wave (Fig. 45). When the ventricle responds alternately to the auricle, there are two *a* waves to each ventricular beat, and these usually fall within the limits of ventricular systole (Fig. 46). In 3:1 rhythm the character of the jugular pulse may be seemingly that of normal cardiac action, and it is particularly in these cases that an electro-cardiographic examination is required to establish the diagnosis. As has been, already noted, complete heart-block is rarely found.

Diagnosis.—The diagnosis of the condition rests on the detection of the extremely rapid contractions of the auricle, and this is not infrequently impossible without the employment of the polygraph or electro-cardiograph; indeed, in some cases a correct diagnosis cannot be made with certainty even though the polygraph be employed, an electro-cardiographic examination being necessary.

We should consider the possibility of auricular flutter whenever an individual is conscious of a marked increase in the cardiac rate, or complains of attacks of palpitation, in either case occurring suddenly and without apparent cause, or suffers from dyspnoea on exertion and other indications of

cardiac failure coming on rapidly, especially if the rhythm of the pulse be regular.

Auricular flutter with continuous 2:1 auriculo-ventricular block should be distinguished from tachycardia associated with the normal rhythm. In

FIG. 45.—Simultaneous tracings of the jugular and radial pulses from a case of auricular flutter, in which the ventricle responded to each auricular contraction. The rate is 188 per minute.

the former, the cardiac rate is not influenced by posture or physical exertion, as is the case in the latter. In some cases of 2:1 flutter, pressure on the vagus causes slowing of the pulse, or even long pauses, especially if digitalis is being administered, and this also is of help in distinguishing it. If the rhythm be irregular, it is necessary to consider whether the case may not be one of auricular fibrillation. In this connection, if a sphygmogram from a case of auricular flutter be carefully studied, it will be found that even though

FIG. 46.—Simultaneous tracings of the jugular and radial pulses from a patient with myocardial and arterial disease, showing the termination of an attack of paroxysmal tachycardia, due to auricular flutter. The first part of the tracing shows auricular flutter, with 2:1 heart-block, the rate of the auricle being 232, and the ventricular rate 116, per minute. The normal rhythm of the heart is resumed after the long pause with the beat 1, 3, 6.

the ventricular rhythm is markedly irregular the pulse-beats measure out in groups of equal length, whereas this is never the case in auricular fibrillation. Pressure on the carotid artery in the neck often causes slowing of the pulse or even long pauses, especially if digitalis is being given. The polygraph and electro-cardiograph are of notable assistance in the differential diagnosis of the two conditions. The diagnosis of auricular fibrillation with a markedly exaggerated ventricular rate in which the irregularity is only slight from auricular flutter should also be considered. Irregularity due to the presence

of extra-systoles should also be excluded. Cases of auricular flutter in which the auriculo-ventricular ratio is constantly 3 : 1 to 4 : 1, so that the ventricular rate is not much, if any, increased, and in which the ventricular rhythm is regular, are easily missed. The employment of the polygraph or electrocardiograph is often necessary in such cases.

Prognosis.—The prognosis of auricular flutter depends upon the frequency and duration of the attacks, the ventricular rate, the condition of the valves, the myocardium, and the vessels, and the results of the administration of digitalis. When once a patient has suffered from an attack of auricular flutter, there is a tendency to its recurrence from time to time. The effect which an attack has upon the heart depends upon the ventricular rate and the degree of integrity of the myocardium; these have been already dealt with. Attacks of loss of consciousness, especially when they occur in the subjects of marked cardiac failure, are attended with danger.

Treatment.—The ætiology should be reviewed, with the object of

FIG. 47.—Simultaneous tracings of the jugular and radial pulses from a patient fully under the influence of digitalis. The auricular rate is 382, and the ventricular rate is 50, per minute.

treating the underlying cause, and the various therapeutic measures applicable for any form of cardiac disorder should be considered.

Apart from this, the treatment of persistent auricular flutter consists of the administration of digitalis or of quinidine. The former should be tried first (see p. 833). After full digitalisation has been obtained, if the auricular flutter still continues, the dosage of digitalis should be gradually diminished to a moderate or even small one, and this continued for a time, in the hope that the flutter may cease. If this is not successful, this method may be repeated after an interval. If the flutter still continues, the question of quinidine, with the object of terminating the condition, should be considered. This subject is dealt with on pp. 838–840. If, on the other hand, full digitalisation induces auricular fibrillation, digitalis may be discontinued for some days, in the hope of a return to the normal rhythm. If this does not occur, treatment resolves itself into the consideration of the employment of digitalis or of quinidine.

The treatment of paroxysmal auricular flutter is that of paroxysmal tachycardia.

The treatment of auricular flutter associated with thyrotoxicosis is discussed on page 964.

NODAL RHYTHM

In nodal rhythm the stimulus for contraction arises in some part of the auriculo-ventricular junctional tissues, travelling upwards into the auricle and downwards into the ventricle, and giving rise to a simultaneous contraction of both auricle and ventricle. The contraction of both chambers may be absolutely synchronous, or the ventricle may begin after, or before, that of the auricle. In the first instance, the *a* and *c* waves of a polygraphic tracing are superimposed, in which case the amplitude of the wave is increased; in the second, the *a* wave precedes the *c* wave, but the *a-c* interval is diminished to about 0.10 sec. The normal rate of the auriculo-ventricular node is less than that of the sinus, so that the pulse-rate is usually diminished, even to 30 per minute. Sometimes, however, there is tachycardia, either persistent, or, more frequently, paroxysmal, the latter being one of the forms of paroxysmal tachycardia.

VENTRICULAR FIBRILLATION

Ventricular fibrillation has been observed. It may be induced experimentally by electric and other kinds of stimuli. Complete and abrupt closure of a coronary artery or one of its main branches, and the action of various poisons, including digitalis, may cause it. The experiments of Goodman Levy have shown that in the cat it is very apt to occur under light chloroform anaesthesia. The condition is preceded by a premonitory period, of varying length, of extra-systoles of special form. A certain number of electro-cardiograms showing ventricular fibrillation in the human subject have been published. Recovery in man is rare. It is believed that ventricular fibrillation is the immediate cause of sudden death in complete and abrupt closure of a coronary artery or one of its main branches, in auricular fibrillation, and some—it may even be most—of the fatalities that occur in chloroform anaesthesia. Unlike auricular fibrillation, the condition is not influenced by increased vagal stimulation.

PAROXYSMAL TACHYCARDIA

The term paroxysmal tachycardia is here employed to denote a condition, not uncommon, in which a marked acceleration of the cardiac rate occurs, which commences suddenly and abruptly and usually without apparent cause, lasts for a varying period, ceases suddenly and abruptly, and is due to an abnormal rhythm—the stimulus for cardiac contraction, instead of arising at the junction of the great veins with the auricle, having its origin at an abnormal point. The return of the cardiac rate to what it was prior to the paroxysm is due to the reversion of the cardiac rhythm to the normal. From the definition given, it will be seen that *paroxysmal tachycardia does not include acceleration of the cardiac rate associated with the normal or sinus rhythm*. It is necessary to explain that under the term paroxysmal tachycardia I include paroxysmal auricular flutter, with marked acceleration of

the ventricular rate and paroxysmal auricular fibrillation with marked acceleration of the ventricular rate, while some authors adopt another nomenclature, using the term "simple" paroxysmal tachycardia to denote paroxysmal tachycardia, and excluding paroxysmal auricular flutter and paroxysmal auricular fibrillation.

It should be noted that the nature of the abnormal rhythm is not always the same; in other words, the conditions which give rise to the paroxysm of tachycardia vary. The point of origin of the new rhythm may be situated in the auricle (Fig. 97), or the auriculo-ventricular junctional tissues—either the auriculo-ventricular node, or the auriculo-ventricular bundle above its division into two branches—or in the ventricle below the division of the bundle (Fig. 98). When in the auricle, the cause of the abnormal rhythm may be paroxysmal auricular flutter with marked tachycardia (Fig. 46), paroxysms of auricular extra-systoles, or paroxysmal auricular fibrillation with marked tachycardia (Fig. 48). In the first instance, in the vast majority of cases the ventricle does not respond to each auricular contraction, partial heart-block being present. When the point of origin is situated in the auriculo-

FIG. 48.—Simultaneous tracings of the jugular and radial pulses, showing the commencement and termination of a short attack of paroxysmal tachycardia, due to auricular fibrillation. The first six beats and the last three in the sphygmogram are regular and due to a normal contraction of the heart. The beats between occur during a period of auricular fibrillation. At *O* a period of 15 seconds has been cut out. (Mackenzie.)

ventricular junctional tissues, there is a simultaneous contraction of both auricle and ventricle; the contraction of both chambers may be absolutely synchronous, or the ventricular systole may begin after, or before, that of the ventricle.

The paroxysms of tachycardia may last only for a few beats, or may persist even up to a few weeks. The patient may experience one attack and never have another, or he may have many in the course of 24 hours, or the attacks may occur at varying intervals, frequent or long, for many years. In those cases due to paroxysmal auricular flutter or paroxysmal auricular fibrillation, persistent auricular flutter or persistent auricular fibrillation may ultimately supervene.

Ætiology.—The ætiology of paroxysmal tachycardia is obscure. It may occur at any age, but usually first occurs during middle life. It appears to be more common in males, and this certainly agrees with my experience. A history of previous infection by rheumatism is not uncommon, and a fair proportion of cases are the subjects of valvular disease, particularly of mitral stenosis, of myocardial degeneration or of thyrotoxicosis, and occasionally it occurs in coronary occlusion, when it is most likely to be of the

ventricular type; but no evidence of organic disease of the heart is found in a large proportion of cases. The condition has been noted in association with focal sepsis, reflex irritation, neurasthenia, the excessive use of tea, coffee, tobacco or alcohol, etc. Among exciting causes are physical exertion, emotional excitement, digestive disturbances—particularly flatulent distension of the stomach or colon, and in one of my own cases the adoption of a certain posture appeared to bring on the attacks.

Symptoms.—When an attack occurs, there is a sudden, abrupt, and marked acceleration of the cardiac rate, usually without apparent cause, while at the end of the paroxysm, there is a sudden and abrupt return to the cardiac rate and rhythm which preceded the attack.

In some cases the patient is able to recognise the onset and termination of the attack. If the attack be brief, he may be unconscious of the tachycardia. If it persists for a time, however, he is usually conscious of it, and generally complains of a fluttering sensation in the chest or, less frequently, of palpitation, and occasionally of a sensation of pulsation in the neck. His face is usually pale and has an anxious expression. The ordinary indications of cardiac failure usually supervene; or, if these were present before the attack, they increase in severity. The degree of failure depends upon the cardiac rate, the duration of the paroxysm and the integrity of the myocardium. In some cases, even when the paroxysm lasts for a day or two, there may be only some limitation of the field of cardiac response, with little, if any, hepatic enlargement or dropsy; while, in long-continued paroxysms, and even in some cases in which the paroxysms last for only a few hours, cardiac failure may be severe or even extreme. As the amount of blood propelled from the neck at each systole is so small as to give rise to cerebral anæmia, the patient may complain of vertigo, and there may be from time to time attacks of faintness or even complete loss of consciousness. Cheyne-Stokes respiration is also not an infrequent symptom when the condition has lasted for some time. In a small proportion of cases, anginal pain occurs.

The cardiac rate is usually above 140 per minute, and very rarely may reach even 300 or more; in the majority of cases perhaps it is between 150 and 190. The pulse is of smaller volume than normal, and its character may resemble that of *pulsus celer*. It may be regular, but it is very irregular when the condition is due to auricular flutter in which the response of the ventricle to auricular contraction is at irregular intervals, or completely irregular when the result of auricular fibrillation. The blood pressure is generally lower during an attack. The jugular veins may be distended, no pulsation visible, or very rapid movements may be evident. A noteworthy feature is the frequent presence of *pulsus alternans*. The results of X-Ray examination show that the heart often becomes actually smaller during short attacks, but in cases in which the attacks are of long duration or the organ is seriously diseased, considerable and rapid—often within a few hours—cardiac dilatation may occur, in which case the physical signs thereof, described on pp. 933, 934, may be noted. If murmurs were present prior to the onset of the attack, they may become faint or even disappear. This applies particularly in the case of a mitral presystolic bruit.

Analysis of polygraphic tracings gives different results according to the nature of the abnormal rhythm.

A remarkable feature of the condition is that with the sudden reversion of the rhythm to normal there is an extraordinarily rapid recovery to the state in which the patient was prior to the paroxysm. In some cases, the cessation of the attack is accompanied by the passage of large quantities of wind and excessive eructations, while a large quantity of urine may be voided.

Diagnosis.—The diagnosis of paroxysmal tachycardia is usually not difficult. The most important factors from the diagnostic point of view are: (1) The commencement and termination of the attack of tachycardia. The suddenness and abruptness of the onset and termination of the tachycardia are characteristic features—the maximum rate is attained within a few seconds, and the return of the cardiac rate to what it was prior to the attack occurs equally quickly; whereas in tachycardia associated with the normal rhythm the onset and termination are gradual. (2) The cardiac rate. A persistent rate of over 160 is almost invariably due to an abnormal rhythm, and a persistent rate of over 140 may be due to the same cause. Tachycardia of a rather less severe grade must certainly not be presumed to be due to an abnormal rhythm. (3) In “simple” paroxysmal tachycardia the cardiac rate is not influenced by posture or physical exertion or pressure on the vagus—unless this causes the paroxysm to cease. Regarding those cases of paroxysmal tachycardia due to paroxysmal auricular flutter with 2:1 auriculo-ventricular block (see p. 879). When paroxysmal tachycardia is due to paroxysmal auricular fibrillation, the cardiac rate is influenced by posture and physical exertion. In each case electro-cardiographic examination will put the diagnosis beyond all doubt.

Prognosis.—The difficulty in forming a prognosis in any case of paroxysmal tachycardia is great. The prognosis may be considered from two standpoints—(1) That of a particular paroxysm, and (2) the question of recurrence of the attacks. With regard to the former, it may be noted that death during an attack is of rare occurrence, although this may occur when the duration of the attack is prolonged. The points which should be taken into account in considering the prognosis of an individual attack are the ventricular rate, the duration of the attack, and the degree of cardiac failure present. When the ventricular rate is not very high, and there is little or no cardiac dilatation, and an absence of œdema of the lungs, hepatic enlargement and anasarca, the outlook is good as far as the risk to life is concerned; while, on the other hand, if the clinical picture be the reverse, the outlook is uncertain, although it should be remembered that the paroxysm may cease at any time, and there is no means of knowing when this may occur, and the patient improves with extraordinary rapidity.

With regard to the question of the recurrence of the attacks, it is impossible to give an answer. For in some cases the patient may never suffer from a second attack; while, on the other hand, they may recur even several times in the course of 24 hours, or at frequent intervals for many years, or, lastly, persistent auricular flutter or fibrillation may supervene even after a few attacks.

Treatment.—This resolves itself into two parts—(1) Prevention, if possible, of the recurrence of the attacks; and (2) treatment during an attack.

With regard to the first of these, a searching inquiry should be made for both the underlying and exciting causes, with the object of treating them.

Sedatives (see p. 833) are often useful. Quinidine, 5 to 15 grains per diem, is frequently successful. Digitalis, either in full or moderate dosage, is occasionally so.

The results of treatment during the attacks are in the majority of cases unsatisfactory. It is true that the paroxysm not infrequently ceases when various remedies are employed, but it should be remembered that the nature of the disorder is to stop suddenly and, therefore, the question of post hoc aut propter hoc arises.

The patient should rest, either in the recumbent position or sitting in an easy chair, and keep warm. The adoption of certain postures, various movements of the body, rapid deep breathing, holding the breath as long as possible, local applications to, or friction of, the chest wall, pressure on the abdomen, a tight abdominal binder, the bringing up of wind, the act of vomiting, pressure on the vagus, particularly the right, or either eyeball with the eye closed may be tried. Failing this, a stiff dose of bromide and chloral; or digitalis medication by the mouth, in such dosage as to produce the full therapeutic effect as soon as possible; or the intravenous injection of strophanthin, may be had recourse to. The last, however, is contra-indicated if digitalis has already been given by the mouth, unless the approximate total amount is known and does not exceed that which is moderate and the dose of the strophanthin should be diminished, and proportionately so according to the total amount of digitalis which has already been administered. Failing these, morphine hypodermically may be considered in those patients in whom there is no reasonable fear of their becoming addicts to the drug. Quinidine, as described in upper part of page 840, has proved successful in some cases of paroxysmal tachycardia, perhaps especially of ventricular origin, complicating coronary occlusion.

FREDERICK W. PRICE.

CARDITIS: THE RHEUMATIC INFECTION OF THE HEART IN CHILDHOOD

Definition.—By carditis is meant inflammation involving the endocardium, myocardium and pericardium simultaneously.

Before dealing with endocarditis, myocarditis and pericarditis individually, it may be advisable to discuss the rheumatic infection of the heart in childhood. This is a subject of the utmost importance, for by far the larger proportion of cases of heart disease under 30 years of age, and a considerable proportion of those of later life, are the direct result of this infection.

It is necessary to point out that it is still not sufficiently realised that it is very easy to overlook a rheumatic infection in childhood, and, even when we are especially on the look-out for it, it is not infrequently very difficult to come to a definite conclusion whether the heart is affected or not. In all probability the reason why infection of the heart by the rheumatic poison is so frequently overlooked, is that the clinical picture of acute and subacute rheumatism was originally drawn from the disease as it appears in adult life, the result being that even now many practitioners do not recognise that rheumatism, as it appears in childhood, presents many and important points of difference.

It is important to bear in mind the following facts : In adult life arthritis is the chief manifestation of the rheumatic infection, and is looked upon as constituting a typical attack, while cardiac involvement is regarded as a complication. In children, on the other hand, arthritis is often vague in character, and may be entirely absent, while affections of other parts are more frequent, and constitute a more conspicuous feature in the disease. Thus, sometimes the affection is confined to the tendons or the fascia in the neighbourhood of the joints. What are called "growing-pains" are frequently of rheumatic origin. Subcutaneous nodules, various erythematata and purpura rheumatica are more frequent manifestations of the rheumatic infection. Chorea is a common indication. Tonsillitis is perhaps more commonly rheumatic than in adult life. There may be unexplained pyrexia. Lastly, cardiac involvement is a much more frequent manifestation of the rheumatic infection in childhood than in adults ; it is at least as frequent an indication as any other, and should not be regarded as a "complication" ; and it may occur in association with any of the foregoing, or with an indeterminate febrile attack, or alone—that is, it may be the only manifestation of rheumatism. Another point to bear in mind is that while rheumatic carditis may occur acutely in children, it often does so in a subacute and insidious form. Not rarely there is a total absence of subjective symptoms. Or, if such be present, they are often masked by other manifestations of the rheumatic infection. Pallor, fatigue, loss of appetite and wasting may be the first symptoms. Sometimes the onset is accompanied by a rise of temperature above that already existing, this increased pyrexia occurring without any increase in the arthritic symptoms. The usual cardiac symptoms may be present (see Endocarditis, Myocarditis and Pericarditis). The diagnosis rests largely on physical signs, and the existence of the condition is frequently unsuspected until the heart is examined. The physical signs, however, are not infrequently slight and vague in character, and the diagnosis is consequently often attended with extreme difficulty.

In view of the foregoing, it is clear that when in a child there is even a suspicion of rheumatic infection, he should at once be put to bed, and a most careful examination of the heart made daily, and if there be any doubt whether the organ is involved or not, he should be kept in bed until this has been set at rest.

In cases in which a definite diagnosis of carditis has been made, a most difficult question which may have to be decided later on is whether there is still *active* carditis or not. In this connection, Schlesinger has pointed out the value of the sleeping pulse-rate. If there is active carditis, the sleeping pulse-rate remains raised and may even equal the pulse-rate when the child is awake, while in the tachycardia of nervous origin, the sleeping pulse-rate is normal. The sedimentation rate of the red blood cells is also used for this purpose. It is increased in the active stages of the disease, and falls to normal when activity ceases.

ENDOCARDITIS

Definition.—By endocarditis is meant inflammation of the lining membrane of the heart. In the great majority of cases the inflammation

~~involves chiefly the endocardium of the valves, and is not infrequently so limited.~~ The term ~~valvulitis~~ is applied to endocarditis of the valves, while inflammation of the endocardium lining the cavities of the heart is referred to as mural endocarditis. The surface of the valves next the blood stream, namely, the ventricular surface of the semilunar valves and the auricular surface of the auriculo-ventricular valves, is affected. In adults the left side of the heart is far more commonly affected than the right, the mitral valve being more frequently attacked than the aortic; while, on the other hand, during fœtal life the opposite is the case. Some degree of myocarditis is probably always present with endocarditis.

A satisfactory classification of endocarditis is not easy, that most commonly adopted being as follows: (1) Acute, (a) simple, and (b) septic, infective, ulcerative or malignant; and (2) chronic or sclerotic. It should be noted that it is impossible to draw a sharp line of distinction between these varieties on grounds of ætiology, pathology, or morbid anatomy. Clinically, however, the distinctive features of each are fairly marked, although even in this case the distinction is not absolute. More recently a subacute variety, ulcerative in character, has been described (see Septic Endocarditis).

ACUTE SIMPLE ENDOCARDITIS

Ætiology.—Acute simple endocarditis occurs most commonly in childhood and adolescence. It is rarely, if ever, a primary disease. ~~Acute and subacute rheumatism, in one of its forms (see p. 886), account for the vast majority of cases.~~ Scarlet fever is not a very infrequent cause. Some are of opinion that the endocarditis, the result of scarlet fever, is identical with that due to rheumatism. Measles, pneumonia, tuberculosis and, in the opinion of some, Bright's disease and diabetes are responsible for a certain number of cases.

Acute simple endocarditis not infrequently occurs in individuals who are the subjects of the chronic or sclerotic form of the disease, so that both acute and chronic endocarditis may be found together.

Pathology.—In this form of endocarditis the parts affected become swollen, as the result of œdema and connective tissue proliferation, and cauliflower-like or warty excrescences, varying in size from that of a pinhead to a bean, called vegetations, make their appearance on the segments of the valve or on the mural endocardium. The valvular vegetations are usually not situated at the extreme margins of the cusps, but at those parts which come into apposition during closure, namely, a short distance from their margins. The vegetations consist of blood platelets, leucocytes and fibrin. In rheumatic endocarditis *Aschoff's nodes* (see p. 329) are sometimes found in the inflamed valves. Various micro-organisms have been described in association with the vegetations, but they are not present in large numbers in the acute simple form of endocarditis. Fragments may become detached from the affected valves, be carried by the blood to remote parts, and ultimately become impacted in a vessel; this process is known as embolism, and the impacted fragment as an embolus. This may result in obstruction of the circulation, and (1) necrosis, or hæmorrhage, or both, within the area of distribution of the occluded vessel, and the formation of infarcts; or (2) gangrene of the area supplied in the case of one of the larger arteries of

the limbs. Infarction most generally occurs in the spleen or kidneys, although it is not infrequently found in the brain or its membranes, the retina, lungs (in right-sided endocarditis), intestines and skin. In cerebral infarction, softening of the area supplied by the affected vessel takes place rapidly, while in pulmonary infarction localised pneumonia is a frequent sequel.

An attack of acute simple endocarditis may be followed by (1) resolution, a rare event; (2) organisation, which is the usual sequel; or (3) ulceration. When organisation occurs, it results in the formation of fibrous cicatricial tissue, which tends to contract as life advances, giving rise to various deformities of the valves and ultimately to permanent stenosis, or incompetence, or both.

Symptoms.—In the first place, the reader is referred to the remarks on p. 886.

Sometimes the onset of acute endocarditis is accompanied by a rise of temperature above that already existing, this occurring without any increase in the symptoms of the causative disease. The degree of pyrexia is usually not marked, but occasionally there is a sharp rise of temperature. The patient may suffer from palpitation, dyspnoea and precordial discomfort or pain. Indications of severe cardiac failure are only met with when the affection is advanced or in cases of severe carditis. Embolism may occur.

The pulse is usually increased in frequency, and is in some cases irregular. The apex-beat may be tumultuous in character, and displaced outwards, and there may also be evidence of enlargement of the area of cardiac impairment transversely; these signs may occur very early in the disease. The first sound at the mitral or aortic area, according to which of these valves is affected, may become slightly prolonged, or roughened, or may exhibit a lack of clearness; within 24 hours it may be accompanied by a distinct murmur, soft in character, the cardiac sound, however, not being abolished. In the case of mitral incompetence, the pulmonary second sound later on becomes accentuated, and may be reduplicated. In the case of the aortic valve, the second sound may become altered, and a soft, blowing, diastolic bruit may subsequently develop; the latter, however, is of much less frequent occurrence during the course of the illness. Reduplication of the second sound and slight accentuation of the first sound at the apex are believed to be early signs of mitral stenosis. A soft, blowing, diastolic bruit in the mitral area is rarely heard during the course of the illness. A mitral presystolic murmur and a short, sharp first sound do not usually make their appearance until some time after the onset of the rheumatic infection, the mitral orifice having become permanently stenosed.

In cases of severe carditis, there may be severe cardiac failure and considerable and rapid cardiac dilatation, even early in the disease.

Diagnosis.—The diagnosis of acute simple endocarditis is often a matter of great difficulty. We should suspect its existence in those cases in which there is an increase in the degree of pyrexia without any aggravation of the symptoms of the causative affection, or when pyrexia persists without any ascertainable cause; or when there is palpitation, dyspnoea, acceleration or irregularity of the pulse, together with the existence of a murmur not previously present.

Increased frequency of the pulse-rate, provided other causes can be excluded, is of considerable diagnostic importance. The same can also be said of the sudden appearance of partial heart-block. When the apex-beat is tumultuous in character it is suggestive of involvement of the endocardium or pericardium. Displacement of the apex-beat and evidence of enlargement of the area of impairment transversely are not necessarily indicative of acute endocarditis, as a certain degree of cardiac dilatation is met with in most of the acute fevers, as the result of toxæmia or anæmia. Neither does a recently developed mitral systolic murmur necessarily indicate endocarditis, for it may be due to anæmia or to simple dilatation. A preliminary prolongation, roughening, or want of clearness of the first sound at the mitral or aortic area is strongly suggestive of valvulitis, as is also the early appearance of the murmur; a murmur which is due to anæmia or to simple dilatation of the left ventricle does not usually make its appearance in the early stages of rheumatism. An aortic systolic is not so suggestive of acute endocarditis as a mitral systolic murmur, while a pulmonary systolic murmur may be almost disregarded. The character of the murmur is of some diagnostic value, a soft blowing, in contrast with a harsh, murmur being in favour of endocarditis. Accentuation of the second sound in the pulmonary area later on in the illness is also suggestive of mitral incompetence. An altered second sound, with later on a diastolic murmur, in the aortic area is indicative of involvement of the endocardium; the latter, however, is rarely heard during the course of an acute illness, and practically never during its early part. The early signs of mitral stenosis have already been noted.

It is necessary to distinguish the murmur of acute endocarditis from that due to previously existing valvular disease. The existence of subcutaneous nodules or pericarditis, the sudden appearance of partial heart-block (indicative of coincident acute myocarditis), or the appearance of new murmurs or the disappearance of old ones, is in favour of a fresh attack of acute endocarditis, whether simple or infective. Embolism is not pathognomonic of acute endocarditis, as it may occur in chronic valvular disease, especially in mitral stenosis. In acute endocarditis, however, it is not infrequently multiple and recurrent, and is of more usual occurrence in the systemic than in the pulmonary circulation.

If acute endocarditis occur in an individual already the subject of valvular disease, the murmur is not of recent development, it is often loud or harsh, audible over a considerable area, and evidence of cardiac enlargement is usually present.

Prognosis.—The immediate prognosis of acute simple endocarditis is, as a rule, favourable, death being of rare occurrence; this may happen, however, if there be accompanying pericarditis or severe myocarditis. With regard to the ultimate prognosis, it has been pointed out that complete resolution in all probability rarely occurs. Organisation is the usual sequel, ultimately giving rise to permanent stenosis, or incompetence, or both; in a certain percentage of these cases, the early murmur may disappear, and a permanent murmur may not become established until much later on, even several years. It should be noted that the future prognosis of a case of acute simple endocarditis largely depends upon whether convalescence is sufficiently prolonged. In a certain number of cases, ulceration of the valve results.

Treatment.—The treatment of a case of acute simple endocarditis is of the greatest importance, especially with regard to the future of the patient. The indications are to endeavour to arrest the morbid processes as early as possible, and to give the heart the best chance of the fullest possible repair.

The treatment of the causative disease should be adopted. For that of rheumatic fever, the reader is referred to pp. 334–336.

In all cases, whatever the cause, absolute rest in bed is indispensable for at least three months, and in some cases for a longer period, after indications of active carditis have disappeared. During this time, the patient should remain in the recumbent posture, keep as quiet as is possible, physically and mentally, and should on no account be allowed to sit upright in bed or get out of bed for an action of the bowels. Afterwards the amount of exertion should be most carefully graduated. At first, an extra pillow may be allowed. A few days later, the back may be slightly raised, and this may be gradually increased until the patient is moved to a couch, to which he should be confined for at least six weeks. After the first two weeks of this period, massage, at first very gently and for short periods only, and gradually increased, may be tried; and after another fortnight, active movements may be tried. Later on, slight walking exercise may be permitted. For some months later, great care should be exercised, and the patient should be given rules as to the amount and kind of exertion; for, on the one hand, exercise may do much harm unless carefully regulated, while, on the other, in moderation it is of great value. If during any of these stages exertion be accompanied or followed by breathlessness, palpitation, fatigue, præcordial discomfort or pain, or *maintained* increased frequency of the pulse, the patient is doing too much, and the amount of exertion should be reduced.

During the active stage of the disease small blisters applied frequently to the præcordium are advocated by some; and during the later stages the internal administration of iodide of sodium is recommended. The results of the administration of digitalis are, as a rule, very disappointing, whether auricular fibrillation (or flutter) is present or not. If it is employed, caution should be exercised and large doses avoided. Strychnine is better withheld in the early stages of the illness when the cardiac action is excited. Adrenaline and pituitary are employed by some in cases in which the blood pressure is very low. In grave cases, the foot of the bed may with advantage be raised to the extent of one or two feet, and recently transfusion has been advised.

Otherwise, the reader is referred to the various therapeutic measures described on pp. 832–847.

CONVALESCENT HOME TREATMENT.—Prolonged convalescence in special country homes devoted exclusively to children recovering from active rheumatic carditis is now advocated. The advantage of this form of treatment is that a return to normal life is made gradually, under skilled supervision, so that any indications of persistent activity of the disease or relapse may be quickly detected, and further complete rest promptly instituted. At some of these homes, facilities also for education are available, and this overcomes one of the greatest drawbacks of prolonged rest in children, namely, interference with education. Though this line of treatment is still on trial, considerable success has been reported in this country and America. A dry and

elevated site is important. At some homes, treatment on the same lines as in the treatment of pulmonary tuberculosis is employed, the wards being so constructed that one side can be opened up. In England such convalescent homes have been organized by the Invalid Children's Aid Society, the London County Council, and the Birmingham Education Authorities.

It is well to examine a patient who has suffered from acute endocarditis at regular intervals after the attack, and careful inquiry should be made as to his mode of life. In children, we should be especially on the look-out for any rheumatic manifestation, and, as soon as detected, the condition should be immediately and adequately treated.

FREDERICK W. PRICE.

SEPTIC ENDOCARDITIS

Synonyms.—Infective Endocarditis; Ulcerative Endocarditis; Malignant Endocarditis.

Objections have been raised against each of these synonyms: that all endocarditis is infective, that ulceration is not invariable, and that some cases recover. But that some distinctive name is necessary to mark off a disease-process which is quite different from "simple" or "rheumatic" endocarditis is generally recognised. The assertion frequently made, that no sharp line of demarcation can be drawn between simple and ulcerative endocarditis, though true, does not dispose of the fact that in the great majority of cases the distinction is of fundamental importance and not very difficult of recognition.

The disease has an importance somewhat out of proportion to its frequency, partly on account of its great gravity and partly on account of the difficulties which often beset the diagnosis. The incidence of the disease in the wards of a large general hospital is about 1 in 170 cases.

Ætiology.—*Relation to rheumatism and other diseases.*—In more than half of all cases of the disease there is a clear history of acute or subacute rheumatism or of chorea. In the majority of these cases the patient has suffered from rheumatic endocarditis some time previous to his present illness, and has been left with definite and recognised valvular disease; in a few the condition of rheumatic endocarditis has passed directly, but often imperceptibly, into that of the ulcerative condition. Usually the interval between the occurrence of the rheumatic fever and the onset of ulcerative endocarditis is measured by several years, and these have been for the most part years of good general health. To those few cases in which the transition between the rheumatic endocarditis and ulcerative endocarditis is a gradual one the term "malignant rheumatism" has been applied by some authorities. But the term introduced confusion in respect of the bacteriological questions involved, and is perhaps on this account to be avoided. Next in frequency to the rheumatic group of diseases in the patient's history, but insignificant in comparison, are scarlet fever, gonorrhœa, influenza, typhoid fever, malaria, syphilis, Graves' disease, dysentery and pneumonia.

Influence of congenital defects.—A congenital defect in the heart predisposes it to infection, apparently through the medium of that chronic thickening of the endocardium which is often found in connection with these defects. This factor has been definitely established in regard to the aortic valve.

Other ætiological factors.—Strain is present in some cases as a definite causative factor. This was seen in a series of cases which occurred in soldiers during the Great War; these cases were aortic in the main, and in several of them there was no evidence of pre-existing valve lesions of an acquired nature.

Age.—The chief incidence is between the ages of 15 and 50. Out of 150 cases collected by the writer 122 occurred between these ages. One-half of all the cases occurred between 20 and 40, no doubt on account of the predisposition created by the presence of sclerosis of the heart valves after acute rheumatism, the chief age incidence of which is a decade earlier than this. The youngest case of the series was that of a child aged $2\frac{1}{2}$ years, the subject of congenital heart defects. The oldest cases were those of a woman aged 64, and of a man aged 63, both of whom developed pneumococcus endocarditis with lobar pneumonia.

Sex.—This does not appear to be a determining factor.

Pathology.—The essential pathology in infective endocarditis is a progressive microbic infection of one or more of the heart valves, or of the mural endocardium. *The infecting micro-organisms*, as judged by positive blood cultures during life rather than by post-mortem investigations, are very variable. An analysis of 40 cases of the disease in which positive blood cultures were made during life showed streptococci in 26, pneumococci and Pfeiffer's bacillus in 5 each, gonococcus in 2, *Staphylococcus albus* in 1, and an unclassified micro-organism of bacillary form in 1. The *gonococcus* accounts for the infection in a few cases. If post-mortem results are taken, *Staphylococcus aureus* bulks largely in the analysis and the pneumococcus is represented more frequently. A few other organisms, relatively unimportant, also appear—*B. typhosus*, *B. coli* and *B. diphtheriæ*. Streptococci are certainly the most common organisms concerned, and the characters of those members of the group found in this disease deserve special attention. If we except acute cases due to *S. pyogenes* (*S. hæmolyticus*), the types of streptococcus most often found are not highly pathogenic, but of low virulence, such as are found in normal fæces and in normal saliva (*S. viridans*). They are for the most part short-chained cocci, not lethal for mice, and they yield a set of biochemical reactions that mark them off quite sharply from *S. pyogenes*. These facts harmonise with certain broad clinical and pathological observations and serve to explain them: the chronicity of many of the cases, and the latency of others; the scanty leucocytosis often seen; the apyrexial periods not infrequently present; the absence of suppuration in the embolic infarcts which is such a feature of the disease; the absence of any visible focus of infection in the great majority of the cases; the enormous number of living micro-organisms that may be present in the blood stream at a time, it may be, when the patient is not acutely ill. The writer has shown that it is not difficult to set up a condition of infective endocarditis in the rabbit by the intravenous injection of "saprophytic" streptococci from healthy human saliva and fæces.

The condition of infection once established in the endocardium, a state of "arterial pyæmia" results, the circulation being fed by micro-organisms from the infected area. Minute vessels become plugged by masses of these microbes. Larger emboli, formed of pieces of the fungating vegetations, and of various sizes, add to the pyæmic process. Destructive and vegetative

processes proceed together at the site of infection, which spreads to adjacent structures in the heart, both by contact and by direct extension. It has been shown that the micro-organisms in the blood stream are destroyed *in vitro* in 24 hours when citrated blood is incubated without culture media. This fact suggests that they are paid out into the blood stream from the heart lesion, but that their duration of life in the former is short. It also explains the fact that blood cultures are not infrequently sterile.

Symptoms and Course.—The disease may be *latent*, and only discovered post mortem. It may be *fulminating*, in which case it may be suspected, but rarely diagnosed. In the fulminating cases the infection is usually by *S. aureus*, and the ulcerating endocarditis is only one part of the *S. aureus* pyæmia. Such is the endocarditis complicating acute osteomyelitis, and that seen in very acute pyæmia resulting from *S. aureus* infections of the skin. The more important types are the *acute* and *subacute*.

The acute form.—The onset is usually abrupt, often with a rigor, and the symptoms are those of an acute specific fever. Pain in, and swelling of, joints is common, with acid sweats, often leading to a diagnosis of rheumatic fever and calling for the use of salicylates. Not infrequently the failure of response to full doses of salicylates is the first observation to throw doubt upon the diagnosis. The pneumococcus cases are generally of this type, pneumonia or pleurisy with effusion being usually present; the patient remains very ill after the eighth day of his disease, infection of the endocardium being perhaps the most serious cause of absence of crisis. Gonococcus infection is also usually of this form. The duration of the acute cases is from 7 to 30 days. A very few cases undoubtedly recover.

The subacute type ("Subacute bacterial endocarditis").—This is probably the most common type of the disease. Attention has of late years been drawn to it by Osler, Horder, Libman and others. The onset is gradual, often insidious, so that it may not be possible to determine with accuracy when the disease began: it seems certain that in many of the cases the process of endocardial infection has existed much longer than is suspected. The initial symptoms are general weakness with sweats and anæmia, or a condition somewhat resembling subacute rheumatism, or fever which is unexplained by the physical signs. The duration of these cases is very variable; from 2 to 6 months includes the majority of them; but a few may last for 12 months or even longer. The infecting micro-organisms are streptococci of the faecal and salivary type (*Streptococcus viridans*, *Streptococcus endocarditidis*), Pfeiffer's bacillus and occasionally the pneumococcus. In some of these cases the pre-existing valve lesion is very slight, although its presence is generally known if the patient is of the private class.

The heart.—In the great majority of cases signs of valvular disease are present at the outset. In a few cases these signs appear during the course of the disease. Rarely, there may be no evidence of valvular disease at any time: this experience is almost confined to cases in which the infection is of a terminal kind, occurring in patients who are too ill to admit of thorough examination, or in whom there is early and considerable dilatation of the heart. As the disease progresses it is common to get evidence of the involvement of other valves than the one originally infected, such as the appearance of signs of aortic regurgitation in a case originally one of mitral disease. Undue importance is perhaps attached to changes heard in the character

of the murmurs from day to day. When the heart symptoms are prominent, the case is said to be of the "cardiac type," and such a clinical picture does quite commonly present itself: in which event the patient has, in most instances, been a heart invalid for some time previously. But in a considerable proportion of the subacute cases it is a striking thing that the heart shows little recognisable defect, at least for a considerable time. For the greater part of its course it may be said that subacute bacterial endocarditis is very largely destitute of cardiac symptoms. Arrhythmia, signs of restriction of the field of cardiac response to effort, and the results of so-called congestive failure—not only may all of these be conspicuous by their absence, it is unusual to see them.

Arterial embolism.—This event is extremely common and constitutes one of the cardinal signs of the disease. *The importance of the search for emboli and their effects in a suspected case cannot be over-estimated.* But to obtain an adequate conception of the disease-process here considered it is necessary to enlarge considerably the earlier notions of the embolic process in two directions: the diffuseness of the embolic site and the minuteness of the embolic fragment. The skin shows two distinct lesions, both highly characteristic of the disease—(a) Petechiæ, varying greatly as to their number in different cases—there may be no more than two or three, and only discovered after careful search, or there may be a great number, presenting an appearance as though the patient has been flea-bitten. (b) Discoloured areas, usually tender, and most often affecting the terminal phalanges, coming and going in the course of a few hours or days. The appearance of one of these red areas is often accompanied by sudden pain or acute tenderness on pressure. These lesions are of considerable diagnostic importance. They do not occur in rheumatism.

In the kidney there may be gross embolic events leading to infarction and hæmaturia. Of equal if not of greater importance is the occurrence of very minute microbic embolisms in the glomeruli, leading to the appearance of red blood cells and traces of albumin in the urine, and ultimately to a state of embolic focal nephritis, demonstrable under the microscope post mortem (Bæhr; Gaskell). The retina may be affected, exploration of the fundus revealing hæmorrhages. One of the most common seats of emboli of the massive kind is the spleen, leading to enlargement and usually a palpable organ. Acute and severe pain may occur with the event, and friction, due to perisplenitis, may be heard. The brain may suffer, the most common result being hemiplegia. The embolus may lead to infective arteritis, with aneurysm formation and hæmorrhage which may be abruptly fatal. The vessels of the limbs are frequently involved, either the main artery, or, more often, their branches, and especially the radial and posterior tibial. Here, again, aneurysms may develop, and gangrene occasionally.

Pyrexia.—Fever is present in nearly all the cases, perhaps in all at some time or other in the course of the disease; but occasional afebrile periods may occur, lasting from 2 or 3 days up to a fortnight, in the subacute cases. In the acute cases a high continued fever is not uncommon, and when this is so the patient is highly toxic and asthenic and the heart symptoms are apt to be in abeyance ("typhoid type"). Irregular remittent fever is the most common form, both in the acute and in the subacute types. A high and regular quotidian intermittent fever is not uncommon—the gonococcus cases

are particularly prone to this variety of fever. Rigors are common in the fulminating and acute cases; they also occur in subacute cases when embolism is rife. Whatever the form of the fever the temperature is apt to take a lower range shortly before death. *A fall in the temperature, the patient remaining very ill, is of no service and must not be taken for a good prognosis.* Such a fall of temperature may occur when signs of renal inadequacy supervene.

The blood shows a progressive and ultimately severe anæmia. The degree of leucocytosis varies with the type of the disease. In acute cases it is generally high (20,000 to 40,000), though this, again, varies with the degree of the patient's response to the infection. In the subacute cases the leucocytosis is rather remarkably constant about the figures 9000 to 12,000. In a few cases there is leucopenia. Blood cultures are extremely important in the matter of diagnosis. And yet it not uncommonly happens in the subacute cases that the diagnosis is certain and no growth of micro-organisms is obtained. In the great majority of cases, however, positive blood cultures are obtained, given proper technique.

General state.—Loss of flesh is invariable, but rarely a marked feature. Pains are common, and are usually arthralgic in character; they are prone to develop suddenly, are rarely accompanied by effusions, and when severe, are most often due to embolic events. The complexion in the subacute cases tends to a *café-au-lait* tint, which is a point of diagnostic value to the trained eye. Clubbing of the fingers is very common, quite apart from the influence of possible old-standing valvular disease. The patients are often singularly optimistic concerning themselves. Libman lays stress upon areas of deep tenderness about the lower end of the sternum and the sterno-costal junctions. Albuminuria is very common, tending to increase with the progress of the disease, and doubtless associated with the focal glomerular nephritis to which reference has already been made.

Modes of Termination.—1. *Recovery.*—A rare event, yet one which certainly occurs at times, even when the diagnosis is beyond doubt.

2. *Death.*—Out of 149 cases studied by the writer, the recorded terminal events occurred in the following order of frequency: heart failure (66), coma (23), sudden death (19), uræmia (18), exhaustion (8), hyperpyrexia (2). Cases dying in coma were for the most part those in which cerebral embolism, with or without hæmorrhage, had taken place. Sudden death was due to perforation of a valve cusp, rupture of aneurysms in the sinus of Valsalva, perforation of the interventricular septum and cerebral hæmorrhage.

Diagnosis.—Evidence of endocarditis, the occurrence of multiple arterial embolism, and the isolation of micro-organisms from the blood stream: the coexistence of these three facts makes the diagnosis of infective endocarditis indubitable. But, as has already been remarked, the diagnosis may sometimes be made quite confidently in the absence of a positive blood culture in certain of the subacute cases. The most important point to establish is the presence of multiple arterial embolism. Seeing that the prognosis is so serious, it follows that a diagnosis of infective endocarditis should never be made unless convincing evidence be forthcoming. In the differential diagnosis the following diseases call for consideration:

1. *Pneumonia.*—There may be considerable difficulty here, seeing that consolidation of the lung is usually present in pneumococcus infection of the

endocardium. Care must be exercised, because hæmaturia and splenic enlargement in a case of pneumonia do not necessarily imply infarction. Nor does a positive blood culture in pneumonia necessarily mean endocarditis. But petechiæ, and the presence of emboli in arteries, in a case in which signs of valvular disease and a positive blood culture are present, justify a diagnosis of ulcerative endocarditis.

2. *Typhoid fever*.—A positive Widal test with a leucopenia may be regarded as almost decisive in favour of typhoid fever. Typhoid infection of the endocardium is very rare.

3. *Rheumatic fever*.—The recurrence of acute rheumatism in a patient who has previously developed valvular disease often gives rise to considerable anxiety on account of the similarity which may exist between the symptoms present and those of pyogenic infection of the endocardium. The rheumatic process may spread itself over several months, salicylates notwithstanding. These difficult cases usually occur in children between the ages of 10 to 16 years. Endocarditis is always present, and often there is pericarditis, or pleurisy, or both. There may be considerable loss of flesh and marked anæmia. The form of the temperature chart rarely affords help. The facts which help to exclude ulcerative endocarditis are the presence of nodules, or of chorea, and the absence of petechiæ, of hæmaturia, of enlarged spleen, and especially of micro-organisms in the blood stream.

4. *Peliosis rheumatica* may cause even greater difficulty, but the condition is uncommon. The association of fever, purpura, anæmia, albuminuria and joint pains in a case of old-standing aortic regurgitation under the writer's care naturally raised fear of infection of the damaged valve cusp. But the purpuric spots and the joint pains were bilateral and symmetrical, there were ecchymoses in addition to the petechiæ, there were effusions into the joints, and blood cultures yielded no growth.

5. *Malaria*.—The resemblance is but superficial, owing to the fact that in some cases of infective endocarditis the fever may be markedly intermittent, and rigors with heavy sweats may occur. The absence of malarial parasites in the blood and the absence of leucopenia are much against a diagnosis of malaria.

6. *Tuberculosis*.—General tuberculosis may be closely simulated by acute ulcerative endocarditis with continued fever when the heart signs are equivocal. But there is leucopenia in general tuberculosis, a sterile blood stream (on repeated culture), and signs of embolism do not occur. Sometimes cases of infective endocarditis find their way into sanatoria for the treatment of phthisis, on the ground that they are cases of "phthisis without physical signs."

Prognosis.—As has already been stated, recovery occasionally takes place in the acute, and still less frequently in the subacute form of the disease. All the same, the diagnosis once definitely established, the outlook is of the gravest, treatment notwithstanding. That the patient is very little affected in general health, that he is extremely hopeful concerning his condition, that the state of the heart in itself gives no cause for concern, and that the number of micro-organisms per c.mm. of blood has fallen very considerably—none of these things should tempt the physician to abate anything from the serious view he takes of the case. Periods of improvement often occur, with or without special lines of treatment, but the fatal issue seems

only to be delayed. It is very difficult to surmise the length of time the patient will live after the diagnosis is made. If there are already present the signs either of renal or of cardiac failure the end is not far off; weeks measure it. Otherwise, developments may proceed quite slowly, and the patient may live some months. But there remain to be reckoned with the various accidents attending upon the dissemination of the endocardial vegetations, or the ulceration of the valves, either of which accidents may bring about a speedy termination. Not seldom, when it seems certain that the course of the disease has been checked, death, more or less sudden, and due to some purely mechanical cause, cheats the physician and those who watch his efforts.

Treatment.—**PREVENTIVE MEASURES.**—Reference has been made to the undoubted fact that the source of the infecting agent in most cases is the mouth or intestine. This suggests that special attention should be directed to these regions in all persons who are the subjects of valvular disease. Oral sepsis of all sorts should receive treatment. Dead teeth, crowned, or not, should be sacrificed. Septic tonsils should be removed. The condition of the intestinal tract should be investigated, and measures adopted to lower the content of streptococci if this appears high.

CURATIVE.—The general (non-specific) measures adopted in the treatment of all cases of septicæmia are applicable here: plenty of fresh air and light, good food frequently administered, and hæmatinic drugs for the anæmia. The writer considers that open-air treatment, as for cases of pulmonary tuberculosis, should be adopted whenever possible. The various measures that have from time to time been tried in order to inhibit the bacterial factor in the disease are the following:

Chemical antidotes.—“Blood antiseptics” have, as a rule, proved very disappointing in the history of the treatment of the disease. Quinine, mercury, arsenic (including salvarsan), carbolic acid, formalin, the sulphocarbolates and many others, whether administered by mouth, subcutaneously or intravenously, lead to no results worth recording. On the other hand, efforts at “sterilisatio magna” of the blood stream are not without immediate danger.

Anti-sera.—As most cases of infective endocarditis are of streptococcal origin, it was hoped that the use of anti-streptococcus serum might lead to cure. The result of a good many trials has been very disappointing. Nor has the use of an autogenous serum, as first attempted by the writer in 1904, led to more than an occasional good result. In conjunction with Hemsted the writer described a case of considerable duration treated successfully by the use of serum from an inoculated donor (1911). The infection was in this case grafted upon a congenital heart lesion. The same may be said in general of the use of anti-pneumococcus serum in the pneumococcus cases. “Immuno-transfusion” has more recently been tried, but so far unsuccessfully.

Inoculation.—The experience of vaccine therapy in this disease is no more cheering than that of serum therapy. Certainly the use of “naked” vaccine has on the whole been singularly disappointing. The writer has not had a case so treated which recovered, although he has seen periods of marked and prolonged improvement which he felt could be attributed to the vaccine.

It would seem that we still lack a scientific method of control of the

disease process by any of the measures yet adopted. It seems clear that cure can only come through inhibition of the bacterial growth in the endocardium, and not merely through cleansing the circulating blood of micro-organisms. This, and a method of detaching the thrombi which hang from the valve cusps in such a fine state of subdivision that no vessel of conspicuous size is obstructed by the particles cast into the blood stream, constitute the therapeutic problem with which the physician is faced. The chief hope would seem to lie in establishing the diagnosis at a very early date so as to employ whatever measures promise success before the vegetations have attained any size and the sub-endothelial colonisation has become established.

HORDER.

CHRONIC OR SCLEROTIC ENDOCARDITIS

Chronic endocarditis is a sclerosis of the valve, and may be—(1) secondary to the acute—especially the rheumatic form, which is the more common event or (2) primary.

Ætiology and Pathology.—When the condition is the result of a previous attack of acute endocarditis, it is more apt to occur in earlier life, the mitral valve being more commonly affected; while if it is primary it is more apt to occur in middle or later life, the aortic valve being more commonly affected than the mitral.

With regard to the ætiology of primary chronic endocarditis, heredity is certainly a factor, and the condition is more common in males, and during or after middle life. Prolonged muscular or mental stress or strain, over-indulgence in food or drink, focal sepsis (see p. 834), the various forms of chronic rheumatism and gout, chronic metallic poisoning—particularly that due to lead, and hypertension are among the most common causes. Chronic renal disease possibly has no direct relation with primary chronic endocarditis, but the associated high blood-pressure is an important causal factor. With regard to syphilis, see p. 947.

When organisation occurs in acute simple endocarditis, the result is the formation of fibrous tissue, which tends to contract as life advances, and as a result there may be thickening, shortening, puckering, chronic vegetations, coalescence of two or more segments, cartilaginous changes, or calcification of the valves; there may also be shortening and thickening of the chordæ tendinæ and apices of the papillary muscles. These structural changes ultimately give rise to permanent stenosis, or incompetence, or both, and there is a tendency in these cases to recurrent attacks of valvulitis, resulting in still greater deformity.

In primary chronic endocarditis there is sclerotic thickening of the endocardium, often occurring in patches, and frequently associated with fatty or calcareous changes, to which the term atheroma is usually applied. There may be thickening, small nodular prominences, shortening, puckering, coalescence of two or more segments, and calcification of the valves; the chordæ tendinæ and apices of the papillary muscles may also be affected. These structural changes also ultimately give rise to permanent stenosis, or incompetence, or both.

Primary chronic endocarditis is frequently associated with atheroma,

which may be widespread. When it affects the aortic valve it may be limited to the valve, or, as is more frequently the case, may also affect the walls of the aorta. In the latter event, diffuse dilatation of the aorta may follow; and the neighbourhood of the mouths of the coronary arteries is often involved, frequently resulting in narrowing or occlusion of one or both of these vessels (see pp. 922, 923).

It may here be noted that foetal endocarditis is usually of the sclerotic form, the right heart being more commonly affected than the left.

Symptoms.—Primary chronic endocarditis produces no symptoms until a certain degree of structural changes in the valves has taken place, when stenosis, or incompetence, or both occur.

FREDERICK W. PRICE.

CHRONIC VALVULAR DISEASE

Definition.—By chronic valvular disease is meant a chronic affection of the cusps of the cardiac valves, or of the orifices, or both. Not only may the orifices and cusps be affected, however, but also the chordæ tendinæ and the muscoli papillares. In many cases the cusps are only secondarily affected; to illustrate this it may be mentioned that incompetence of a valve may be due entirely to dilatation of its orifice, or, in the case of the auriculo-ventricular valves, to an affection of the muscoli papillares or chordæ tendinæ. Whatever the nature and form of the valvular lesion, it gives rise to stenosis or narrowing, which results in obstruction to the flow of blood; or to incompetence, which allows of regurgitation; or frequently to both of these together. Along with the valvular lesions there are usually coincident changes in the cardiac musculature, the aorta, or coronary arteries.

THE RELATIVE PROPORTION AND THE COMBINATIONS OF THE DIFFERENT VALVULAR DISEASES.—It should be noted that not infrequently more than one valve is involved at the same time, especially in the case of rheumatic valvular disease.

The mitral is the valve most commonly affected, and incompetence of this valve is more frequent than stenosis. When mitral incompetence results from a previous attack of acute endocarditis, there is usually some degree of stenosis as well; when it is of the *relative* variety, it is often associated with tricuspid incompetence. Pure mitral stenosis is comparatively infrequent; in the process of thickening and contraction, there is usually some degree of incompetence. Aortic regurgitation is very common; a greater or less degree of stenosis, however, not infrequently accompanies the incompetence. Pure aortic stenosis, on the other hand, is one of the rarest of valvular affections. Disease of the pulmonary valve is comparatively rare, and is usually of congenital origin. Pulmonary stenosis is one of the most frequent forms of congenital heart disease; as an acquired condition, it is very rare. Pulmonary incompetence is the rarest of valvular lesions. Tricuspid incompetence is the most common form of right-sided valvular affections. In the vast majority of cases it is of the *relative* variety, in which case it is a common result of mitral disease. Tricuspid incompetence is rarely primary, and then stenosis is usually present with it and also mitral or aortic disease. When

tricuspid incompetence occurs alone it is in all probability congenital. Tricuspid stenosis is comparatively rare, but not so rare as was formerly supposed; the acquired form is usually associated with mitral stenosis.

In chronic valvular disease due to acute or subacute rheumatism, the following is the order of frequency: mitral disease alone; mitral and aortic disease; aortic disease alone; mitral and tricuspid disease.

Ætiology.—Chronic valvular disease may be of congenital origin (*vide* Congenital Heart Disease), or may be due to a previous attack of acute endocarditis resulting in chronic endocarditis, or to primary chronic endocarditis, new-growths, traumatism, or, in the case of the aortic valve, to syphilitic mesaortitis. This list does not include *relative* incompetence of a valve. The causes of acute endocarditis, and also of primary chronic endocarditis, have been fully dealt with. When chronic valvular disease is due to a previous attack of acute endocarditis, it is more apt to occur in early life, and when due to primary chronic endocarditis in middle or later life. Neoplasms may arise from the walls of the heart or from the valves. They rarely cause obstruction. A traumatic lesion of a cusp or of the chordæ tendinæ, the result of excessive physical exertion, may cause stenosis or incompetence of a valve, and is of much more common occurrence in the case of the aortic than the mitral valve. It rarely takes place, however, in the absence of pre-existing disease of the valve.

In *relative* incompetence of a valve the cusps themselves are healthy. This is more common on the right than on the left side of the heart, and is almost unknown in aortic disease, and is not nearly so frequent as in the case of the mitral valve. The condition may occur from the following causes: (1) Dilatation of the cavity of the ventricle—this produces an alteration of the relation of the cavity and of the cusps, the segments of which cannot properly approximate, with consequent regurgitation through the orifice. (2) Enlargement of the orifice on account of relaxation of the surrounding muscular structures; in these cases the tonicity of the muscular ring is impaired, and the cusps do not completely come together. (3) Enlargement of the ventricular cavity and dilatation of the orifice combined. (4) Shrinkage or stretching of the muscoli papillares or chordæ tendinæ as a result of disease.

Pathology.—See Chronic Endocarditis and Syphilitic Mesaortitis.

EFFECTS OF VALVULAR DISEASE UPON THE WALLS OF THE HEART AND OTHER ORGANS.—In the case of stenosis of a valve, there is beyond the narrowed orifice a tendency to a diminished blood supply. As the progress of the narrowing of the orifice is, as a rule, slow, the muscular wall of the chamber immediately behind the orifice usually hypertrophies, this process enabling the chamber to overcome the obstruction. In a large majority of cases there is also dilatation, owing to the fact that the cardiac chamber has to accommodate a larger amount of blood than normal. In the case of valvular incompetence, on the other hand, there is not necessarily a diminished blood supply beyond the orifice. The cavity immediately behind the orifice has to accommodate the regurgitant stream of blood in addition to the normal amount of blood arriving in the normal manner, and, therefore, an increase in its capacity is necessary; in other words, dilatation occurs. This excess of blood must be propelled with each systole of the chamber, with resultant hypertrophy of the muscular wall. It can be readily under-

stood that in order to maintain the circulation adequately it is necessary that a larger quantity of blood be propelled, in order to compensate for the amount of blood which regurgitates. In this way dilatation with hypertrophy ensues, the former being greater than in the case of pure stenosis.

Passing to the consideration of the different valvular lesions :

In mitral stenosis the strain falls mainly on the left auricle and the right ventricle. The left auricle enlarges as the result of both hypertrophy and dilatation. Occasionally when its wall is diseased, that chamber dilates to aneurysmal proportions, extending to the right as far as the chest wall. The right ventricle hypertrophies and, later, dilates. The increased pressure in the pulmonary circulation is raised, and the pulmonary artery and its branches are consequently dilated and sometimes become atheromatous. Relative pulmonary incompetence may supervene, due to dilatation of the orifice and adjacent part of the pulmonary artery. Enlargement of the left auricle, the pulmonary artery, and the right ventricle can

FIG. 49.— Orthodiagram from a case of mitral stenosis, showing enlargement of the left auricle, which projects to the right, and enlargement of the pulmonary artery and infundibular part of the right ventricle on the left border of the heart. A, aorta; PA., pulmonary artery; R.V., infundibular part of the right ventricle; L.V. left ventricle; L.A., left auricle; R.A., right auricle.

usually be made out by X-Ray examination. The left auricle projects backwards and to the right, and the infundibular part of the right ventricle and the pulmonary artery project above the left ventricle on the left border of the heart (Fig. 49). In cases in which auricular fibrillation with cardiac failure is present, the right auricle becomes increasingly enlarged (Fig. 50). Ultimately relative tricuspid incompetence, and dilatation and hypertrophy of the right auricle, supervene. When mitral incompetence is also present, in addition to the foregoing, the left ventricle is enlarged, the result of both hypertrophy and dilatation.

In aortic valvular disease the strain falls on the left ventricle. In stenosis the left ventricle hypertrophies, it may be to a considerable degree and, later,

dilates. In aortic incompetence, dilatation and hypertrophy of the left ventricle takes place, which may even be very marked. On X-Ray examination in aortic valvular disease, the enlargement of the left ventricle is shown by extension of the heart to the left, and increased convexity of the left

FIG. 50.—Orthodiagram from a case of mitral stenosis and auricular fibrillation with cardiac failure.

border (Fig. 51), and in the case of incompetence the latter may exhibit exaggerated pulsation. The degree of dilatation of the left ventricle may increase until ultimately, owing to dilatation of the ring supporting the mitral valve, relative incompetence may occur. When aortic valvular

FIG. 51.—Orthodiagram from a case of aortic incompetence, of rheumatic origin, showing enlargement of the left ventricle.

disease is due to syphilis, there may be, in addition, characteristic changes in the shadow of the aorta, described on page 949.

In pulmonary stenosis the right ventricle hypertrophies, it may be in marked degree, and, later, it dilates. In pulmonary incompetence, hypertrophy and dilatation of the right ventricle, and usually of the right

auricle, also occur. In tricuspid stenosis there is hypertrophy and dilatation of the right auricle; while in tricuspid incompetence dilatation and hypertrophy of this chamber take place. There may follow dilatation of the venæ cavæ and their tributaries, and consequent chronic venous congestion and other systemic changes, as already described on p. 827.

Mitral disease is apt to cause dilatation of the pulmonary veins and capillaries, with resultant chronic venous congestion and œdema of the lungs, dilatation of the pulmonary artery, and subsequent changes in the right side of the heart. Valvular disease of the right side of the heart is apt to cause dilatation of the venæ cavæ and their tributaries, and consequent cyanotic changes in the liver, spleen and kidneys, chronic venous congestion and catarrh of the mucous membranes of the hollow viscera, œdema or anasarca, and transudation of fluid into the serous sacs.

MITRAL STENOSIS

Ætiology.—Mitral stenosis is always organic. It commences much more commonly in early life, and is much more frequent in females than in males. In the great majority of cases it is the result of an antecedent attack of acute endocarditis, due to rheumatism or scarlet fever. In a certain proportion of cases it originates in adults as a result of primary chronic endocarditis. In others the ætiology is obscure.

Pathology.—In mitral stenosis the commonest type of lesion is for the cusps to be united by their margins; but it may be situated elsewhere, as, for example, at the level of the auriculo-ventricular ring. When the lesion consists of a union of the margins of the cusps, two well-marked types of stenosis may result—(1) The “funnel-shaped mitral,” which is more common in childhood; and (2) the “button-hole mitral,” which is by far the more common in adults and persons of advanced years.

In the former, the united cusps form a funnel-shaped membrane which projects downwards into the left ventricle, the wide mouth of the funnel being situated at the ring, and the smaller end being drawn down towards the apex of the heart, by shortening of the chordæ tendinæ and papillary muscles. In the case of button-hole stenosis, the united cusps form a diaphragm, perforated by a narrow slit-like aperture, which almost closes the orifice. A combined form, that is, a funnel having a narrow slit at its lower end, instead of a circular aperture, has also been described.

Symptoms.—In mitral stenosis there may only be dyspnoea, palpitation, fatigue, or præcordial discomfort or pain on severe physical exertion. Later, these symptoms are induced by less and less effort. Cough is a frequent symptom, the patient is liable to attacks of bronchitis and broncho-pneumonia, and epistaxis, hæmoptysis and infarction may occur. Embolism is of more frequent occurrence in mitral stenosis than in any other variety of chronic valvular disease. There is often a persistent dusky flush over the cheeks, clubbing of the finger-ends, and gradual loss of flesh, and, in the young, stunted growth is sometimes to be noted. Later, there may be lividity of the lips, ear-tips and cheeks, and puffiness around the ankles in the evening. Ultimately there may be indications of severe, or even extreme, cardiac failure. The symptoms of cardiac failure in mitral disease are principally pulmonary, and those of systemic venous congestion, and much

less those of systemic anæmia, or angina pectoris. Sudden death is rare, a fatal termination being usually the result of gradual cardiac failure.

The subjects of mitral stenosis are liable to subacute and acute rheumatic attacks.

Usually the pulse is small, the upstroke being short and soon attaining its maximum, the pulse-wave is long, and diastolic is absent (Fig. 52). The maximum blood-pressure is usually rather below the normal, but the minimum pressure is rather high, so that the pulse is full between the beats. When cardiac failure supervenes, both the systolic and diastolic pressures fall. The complete irregularity of the pulse which is associated with auricular fibrillation is often found in mitral stenosis with cardiac failure.

On inspection and palpation the following points may be noted in cases of pure mitral stenosis. The apex-beat may be in the normal position or displaced. The displacement is usually directly to the left. The apex-beat may be normal, diffuse or indefinite, or may be in the form of a peculiar sudden tap communicated to the fingers, which is very characteristic. In many cases there is a thrill, having its maximum intensity at the apex or somewhat nearer the parasternal line. This may be absent at some periods and present at others; it may be absent when at rest, and in evidence after exertion or when the arms are extended. Examination for the characteristic

FIG. 52.--Sphygmograms from cases of mitral stenosis.

thrill and murmur of mitral stenosis should be conducted with the patient lying on his back, on the left side, sitting up and inclined forwards, standing up with the arms extended, and after gentle exercise. The thrill is usually presystolic in time, but may be diastolic. When presystolic, on palpation of the præcordium there is a sensation communicated to the hand resembling that produced by the purring of a cat. Sometimes an impulse may be made out at the base of the heart, coincident with the closure of the semilunar cusps, with its maximum intensity in the second left intercostal space. In the large majority of cases a murmur is present. This may be audible at some times and not at others. It is heard at the apex, or between this point and the left border of the sternum. The murmur is usually presystolic in rhythm; as in the case of the presystolic thrill, it is due to the systole of the auricle driving blood through a narrowed orifice, and disappears with the onset of auricular fibrillation. The murmur is almost invariably rough; it may be harsh and vibratory, and this quality of the murmur is almost pathognomonic. The first sound which terminates the murmur is altered in a characteristic way, to be described later. *The locality of the murmur is almost always very limited, and the area may not be larger than 1 inch in diameter; this should be particularly noted, because it accounts for the fact that the lesion is so often unrecognised.* Instead of presystolic the bruit may be diastolic in time. Diastolic murmurs tail off, and do not have, as a rule, the harsh and vibratory character of the presystolic bruit; they are, instead, soft

and blowing in type, and are due to the passive inflow of blood from auricle to ventricle. There may be a combination of two murmurs; there may be a long murmur beginning immediately after the second sound, and continuing all through ventricular diastole and auricular systole, the early part being diminuendo and the latter part crescendo. Or, at one time, there may be a presystolic, and at another time a diastolic, murmur. Sometimes a diastolic murmur, usually soft and blowing in character, with its point of maximum intensity in the pulmonary area, due to *relative* pulmonary incompetence (the Graham Steel murmur) is to be heard. The first sound becomes short, sharp and clear, like a sudden snap, resembling the second sound. As mitral stenosis is usually accompanied by incompetence, a mitral systolic murmur is usually audible. The second sound is usually accentuated, particularly in the pulmonary area, and may be reduplicated. In a later stage of the disease the second sound at the apex may disappear, the short, sharp first sound may become louder, and the murmur become more frequently diastolic in time. In the absence of a diastolic, as well as of a presystolic, murmur, all that is audible at the apex now is the altered first sound. The physical signs of hypertrophy and dilatation of the left auricle and the right ventricle (see elsewhere) may be present.

For results of X-Ray examination, see pp. 901, 902.

When cardiac failure supervenes, the pulse-rate increases, the apex-beat becomes diffuse and less forcible, the transverse area of cardiac impairment increases, and the signs of tricuspid incompetence may be present.

Diagnosis.—When characteristic signs of mitral stenosis are present, the diagnosis is easy. The results of X-Ray and electro-cardiographic examination are also of value. The thrill is almost pathognomonic. Some writers believe that a similar thrill may be present in aortic incompetence, and therefore that this affection should always be first excluded. The thrill must be distinguished from a mere vibration of the chest wall, which may be occasioned by a forcibly acting heart when the ribs are rigid. In this case, by separating the fingers and placing them in the intercostal spaces the osseous vibrations are not felt. In some cases there is from time to time a complete absence of a thrill and murmur. (In the latter case we are justified in inferring that in all probability mitral stenosis is present from the character of the pulse and first sound, together with evidence of hypertrophy of the right ventricle, and accentuation or reduplication of the second sound.) Some writers are of opinion that a rumbling presystolic bruit is sometimes heard in the case of adherent pericardium in children. Even if this be so, the bruit is not rough and vibratory in character, neither does it terminate abruptly at the first sound, nor is the first sound modified in the way already described, and, further, there are usually definite physical signs of adherent pericardium. The question whether mitral stenosis is present in addition to aortic incompetence has occasionally to be considered. In this connection it may be noted that Flint's murmur has not the harsh and vibrating character which is commonly found in a presystolic bruit due to mitral stenosis, and if a thrill be present it is not "purring" in character. It should be borne in mind that both lesions may be present at the same time, and, therefore, it is sometimes difficult to say whether the murmur is that described by Flint or one due to the presence of mitral stenosis. In coming to a decision, the character of the murmur, the thrill and the pulse—the characteristic collapsing pulse of

aortic incompetence being modified if mitral stenosis be present as well—will be of assistance.

Mitral stenosis is sometimes unrecognised in cases in which there is associated incompetence; the presystolic murmur, instead of ending in the first sound, ends in a systolic murmur, and a diagnosis of a long systolic murmur is erroneously made. There is, however, a difference in character between the former and the latter parts of this continuous bruit, the earlier portion being rough and vibratory in character, and the latter blowing or musical. Further, we can observe the position in the cardiac cycle of the two parts of this continuous murmur by placing the fingers upon the apex-beat or over the carotid artery. When the second sound at the apex has disappeared, the presystolic murmur may be mistaken for a systolic murmur, and the modified first sound for the second sound. In this event a differential diagnosis can be made from the difference in character of the two murmurs, from the fact that a presystolic murmur ends, while a systolic murmur begins, with an accent, and by timing the murmur in the manner already indicated. When, in addition to the absence of a second sound at the apex, there is also no bruit present, mitral stenosis may not be diagnosed, and a diagnosis of dilatation of the left ventricle made; in dilatation, however, a second sound is audible.

The differential diagnosis between aortic incompetence and mitral stenosis has already been discussed. A differential diagnosis may have to be made between tricuspid and mitral stenosis. In the case of the former, the point of maximum intensity of the thrill and murmur is in the tricuspid area. Occasionally a mere reduplication of the first sound is mistaken for mitral stenosis.

Prognosis.—Mitral stenosis ranks after aortic incompetence in gravity among the chronic valvular lesions, and the prognosis is much less favourable than in the case of mitral incompetence.

There is apparently a tendency for mitral stenosis to be progressive, pulmonary complications are frequent, and embolism is relatively frequent. When the lesion occurs in the early years of life, physical and mental development are apt to be retarded, and the patient is liable to fresh attacks of rheumatic valvulitis. The prognosis depends upon, among other things, the degree of stenosis, which when considerable is almost invariably accompanied by incompetence. The supervention of a diastolic murmur marks a downward grade. Sudden death is of rare occurrence, a fatal termination being usually the result of gradual cardiac failure, which in most cases is associated with the supervention of auricular fibrillation.

Treatment.—This (together with that of the other forms of chronic valvular disease) will be discussed later.

MITRAL INCOMPETENCE

Mitral regurgitation may be organic or relative, the latter being also termed functional.

Ætiology.—When organic, by far the most common cause is a previous attack of acute endocarditis, but sometimes it is due to primary chronic endocarditis. Rarely it is due to trauma, in which case there is usually a rupture of a chorda tendinea or of a cusp. *Relative* incompetence is a

somewhat common cause of mitral regurgitation. It may be due to acute febrile affections, aortic valvular disease, hypertension, chronic Bright's disease, acute myocarditis, chronic myocardial disease and anæmias.

Symptoms.—In by no means an inconsiderable proportion of cases the disease is latent throughout the whole course. When symptoms are present the clinical picture resembles that of mitral stenosis; it should be noted, however, that hæmoptysis and embolism are of less common occurrence.

When the lesion is slight, the pulse, as a rule, scarcely differs from the normal. When the lesion is considerable, the amplitude is apt to be smaller than normal, the upstroke rather steep, there is often very considerable diastolic murmurs, the pulse being easily compressible and not felt between the beats, and the blood-pressure is low. The complete irregularity which is associated with auricular fibrillation is often found in mitral incompetence with cardiac failure. In mitral incompetence, due to organic valvular disease, indications of hypertrophy of the left ventricle (see p. 930) are usually to be noted. On auscultation a systolic murmur is audible. This usually commences with the first sound, which it may replace or merely accompany, and may extend all through the short pause; rarely it follows the first sound. Its point of maximum intensity is at or near the apex-beat, and its direction of selective propagation towards the axilla and the angle of the scapula. Occasionally it can be heard over the whole chest. The area of conduction of slight mitral systolic murmurs is frequently not large. A mitral systolic murmur is usually soft and blowing, occasionally musical, and more rarely rough and grating. It is usually louder when the patient lies down, and becomes feebler in the sitting or standing posture; in any doubtful case, therefore, the patient should be examined in these several positions. The second sound at the pulmonary area is, in the great majority of cases, accentuated, and may be reduplicated. Physical signs of hypertrophy and dilatation of the left auricle and the right ventricle (see elsewhere) may be present.

When cardiac failure supervenes the pulse-rate increases, the apex-beat becomes less forcible, the transverse area of cardiac impairment increases, and the signs of tricuspid incompetence may be present.

In *relative* mitral incompetence the apex-beat may be displaced outwards, but not downwards, and instead of being more forcible than normal it is usually less so. The systolic murmur is, as a rule, not propagated beyond the mid-axillary line, and there is often no accentuation of the pulmonary second sound.

For results of X-Ray examination, see p. 901.

Diagnosis.—It is necessary to point out that a systolic bruit audible over the apex of the heart is not infrequently erroneously interpreted as indicative of organic disease of the mitral valve, when in reality the murmur is functional. In order to say that a mitral systolic murmur is indicative of organic mitral incompetence, we must satisfy ourselves that certain other physical signs are present. With this object in view, it is advisable to note—(1) The position and character of the apex-beat; (2) the area of propagation of the murmur; and (3) the existence or absence of accentuation of the pulmonary second sound. In the case of a mitral systolic murmur, due to organic valvular disease, owing to the presence of hypertrophy of the left ventricle, the apex-beat is usually displaced downwards as well as outwards. When the degree of valvular disease is so slight that no definite downward

displacement of the apex-beat is present, its force is almost invariably increased, whereas in functional conditions it is apt to be less forcible than normal. If the murmur be propagated towards the angle of the scapula beyond the mid-axillary line, we may be practically certain that it denotes the existence of organic disease. A definite accentuation of the pulmonary second sound, provided there is no condition of the lungs to account for it, is in favour of the view that we are dealing with organic disease. The diagnosis is further strengthened by evidence of the existence of mitral stenosis. The diagnosis of relative mitral incompetence, the result of aortic valvular disease, hypertension, chronic Bright's disease and chronic interstitial myocarditis from organic mitral incompetence is very difficult, for these affections themselves give rise to hypertrophy of the left ventricle. The history of the case is of importance.

In addition to the points of differential diagnosis just enumerated, murmurs due to anæmia, and cardio-pulmonary or cardio-respiratory murmurs, have other distinguishing features. Hæmic murmurs are always systolic in time, and are most frequently heard in the pulmonary area, next most commonly in the mitral area, the tricuspid area and the aortic area—in the order named, the last being comparatively rare. The “bruit du diable” is frequently present as well. Murmurs related to respiration are not absolutely synchronous with the beginning of systole or diastole, and may proceed or follow either; the point of maximum intensity does not coincide with any valvular area, the murmurs being usually heard best over the margins of the lungs; and they vary with the phases of respiration.

Prognosis.—The prognosis of mitral incompetence is more favourable than that of aortic stenosis or incompetence, or mitral stenosis. If the lesion be slight and the conditions of life favourable, the individual may even live to the normal span of life without experiencing much, if any, inconvenience. When, on the other hand, the lesion is severe, as indicated by marked cardiac enlargement, and more especially when symptoms of cardiac failure are present, the patient may live only for a few years. It should be remembered, however, that even when considerable or marked cardiac failure exists, if rest and other suitable therapeutic measures be adopted, the patient may improve for a considerable time. In attempting a prognosis, we should note, among other things, the pulse-rate, the degree of displacement of the right margin of cardiac impairment, and the existence or otherwise of any indications of venous stasis.

With regard to the prognosis of mitral regurgitation, due to *relative* incompetence, this depends upon the cause.

MITRAL STENOSIS AND INCOMPETENCE (DOUBLE MITRAL DISEASE)

It has been already explained that when mitral incompetence results from a previous attack of acute endocarditis, there is usually some degree of stenosis as well, and also that pure mitral stenosis is comparatively infrequent, as it is usually accompanied by incompetence. We thus get the double lesion.

Ætiology.—This is the same as that of mitral stenosis.

Symptoms.—The symptoms partake of the character of both lesions. Auricular fibrillation, cardiac failure, and tricuspid incompetence are more likely to supervene than in the case of a single lesion. There is usually con-

siderable enlargement of the heart, and on auscultation the combined murmurs may be heard, but not infrequently a mitral systolic is the only murmur present. Accentuation of the pulmonary second sound is usually more marked than in the case of a single lesion.

AORTIC STENOSIS

Aortic stenosis may be absolute or relative. In absolute stenosis the orifice is less than its normal size, while in relative stenosis the size is normal, but dilatation of the aorta just above the valve is present.

Ætiology.—Aortic stenosis is more commonly found in middle or later life, and in males. Absolute stenosis is almost always the result of an antecedent attack of acute endocarditis, due to rheumatism or scarlet fever, in which case the mitral valve is also, as a rule, similarly affected. It is, however, sometimes due to primary chronic endocarditis, and is, for this reason, more common in middle or later life, and in males, while sometimes it is of congenital origin. Relative stenosis, due to general dilatation of the aorta just above the valve, may be caused by syphilis or atheroma.

In adults with aortic incompetence of rheumatic origin, some degree of stenosis is common; usually the latter is of moderate grade, but occasionally it is extreme.

Symptoms.—For the symptoms of syphilitic aortitis, see pp. 947–949.

FIG. 53. —Sphygmogram from a case of aortic stenosis.

When aortic stenosis is the result of a previous attack of acute endocarditis, the subjective symptoms are, as a rule, delayed, and, indeed, the condition may be latent all through life.

The most common symptom of aortic stenosis is shortness of breath on exertion. Symptoms of cerebral anæmia (see pp. 826, 827) are much more apt to occur early than in mitral disease, while præcordial pain is more frequent, and angina pectoris much more likely.

The symptoms of relative mitral incompetence may supervene.

The pulse is sometimes very characteristic; indeed, not infrequently, the diagnosis of the lesion is greatly assisted by the peculiar character of the pulse. In moderate degrees of stenosis the pulse may not show any striking abnormal features. As the lesion increases, however, it becomes infrequent, and the sphygmogram shows a pulse of smaller amplitude, the percussion wave is oblique, and the summit is gradual and slow, while to the finger the pulse is full between the beats (Fig. 53). It may be anacrotic, or of the bisferiens type. When, in addition to stenosis, aortic incompetence is present, which is not uncommon, the pulse which is characteristic of the former will be modified by the latter condition. The blood-pressure is variable; it tends to be subnormal, but is often supernormal, as the result of coexisting arterial disease, or chronic interstitial nephritis. The diastolic pressure is high relative to the systolic, and the pulse pressure is diminished. When aortic stenosis is associated with atheroma, as is frequently the case, the vessel wall may be thickened and tortuous.

Almost always there are physical signs of hypertrophy of the left ventricle. A characteristic sign of aortic stenosis is a gradual, slow rise of the apex-beat—a "slow heave,"—which is sustained. A thrill, systolic in time, is often palpable; this has its maximum intensity in the aortic area, and may be felt over the whole præcordium, and, indeed, sometimes all over the chest and the large vessels of the neck. On auscultation, a systolic murmur is audible, with its point of maximum intensity in the aortic area, or over the manubrium sterni, or to the left of the sternum. The murmur, however, may be audible all over the chest, and even at the back, in which case it is loudest at the level of the fourth vertebra close to the left border of the spinal column. The direction of selective propagation is upwards along the vessels of the neck. It is usually loud, and has been heard several feet away from the patient. It is generally rough and grating, but may be musical, or rarely blowing. The second sound in the aortic area varies considerably in loudness, largely according to the nature of the lesion of the valve (for example, the fusion of the cusps may be such as not to allow such apposition as is necessary to cause an aortic second sound), and the presence or absence of arterial disease. It is usually diminished and may be practically absent, but occasionally may be louder than normal. Physical signs of dilatation of the aorta are sometimes also present.

For the results of X-Ray examination, see p. 902.

Later, the physical signs of relative mitral incompetence may be present.

Diagnosis.—For the diagnosis of syphilitic aortitis, see pp. 949, 950.

It is necessary to point out that it is not justifiable to make a diagnosis of aortic stenosis from the mere presence of a systolic murmur over the aortic area, additional evidence being required, as the murmur may be due to other causes.

A diagnosis of aortic stenosis can readily be made when the characteristic pulse and apex-beat, an aortic systolic thrill and murmur, with the direction of selective propagation upwards along the vessels of the neck, and a diminished or absent second sound is present. When, however, only one or few of these features are present, difficulty with regard to the diagnosis may easily arise. An anacrotic pulse is characteristic, but not pathognomonic; nevertheless, it is of greater diagnostic value than *pulsus bisferiens*. While the presence of a thrill is a valuable diagnostic sign, it may also be found in circumscribed aneurysm of the aorta. A systolic murmur with the direction of selective propagation upwards along the vessels of the neck is at least strongly presumptive, and, in the opinion of some, is almost sufficient evidence. Before arriving at a diagnosis of absolute stenosis, unless a typical pulse is present, X-Ray examination for dilatation of the aorta is necessary.

Certain conditions must be excluded in considering the diagnosis of aortic stenosis; among these are bruits due to anæmia, cardio-pulmonary or cardio-respiratory murmurs, general dilatation (diffuse aneurysm) of the aorta just above the valve, circumscribed aneurysm, pulmonary stenosis, patent ductus arteriosus, and pressure upon the aorta by a mediastinal tumour in which no definite pulsation is present.

The distinguishing features of murmurs due to anæmia and murmurs related to respiration have been discussed on p. 908. In general dilatation of the aorta just above the valve, the murmur is often heard over the vessels of the neck, but occasionally the area of impairment at the level of the second

and third intercostal cartilages extends farther out to the right than the normal limit, and the second sound is not only accentuated, but also is low-pitched, ringing, and usually audible over a much wider area. As a rule, there is little difficulty in diagnosing aortic stenosis from circumscribed aneurysm. It is unnecessary to point out the value of X-Ray examination in the diagnosis of both forms of dilatation of the aorta. One point alone is sufficient to distinguish aortic stenosis from pulmonary stenosis; in the latter the murmur is never propagated into the arteries at the root of the neck. Further, the character of the respective pulses differs materially, while in aortic stenosis there is evidence of hypertrophy of the left, and not of the right, ventricle, and the apex-beat may be characteristic.

Prognosis.—The prognosis of aortic stenosis depends mainly on the ætiology, the degree of the lesion, whether it is stationary or progressive, and the condition of the myocardium, the aorta and the coronary arteries. Some authorities are of opinion that when the affection is due to antecedent acute endocarditis, the outlook is even more favourable than in mitral regurgitation. When it is the result of primary chronic endocarditis, the prognosis is less favourable, as the lesion is more likely to be progressive, and to be associated with chronic myocardial disease, and atheroma of the aorta and even of the coronary arteries. If syphilis is responsible for the lesion, the outlook is much worse.

AORTIC INCOMPETENCE

Ætiology.—Aortic incompetence is more commonly found in middle or later life, and in males. There are three main causes. (1) A previous attack of acute endocarditis, in which case the mitral valve is, as a rule, similarly affected. This is the commonest cause of the condition in young adults. (2) Syphilitic mesaortitis. This usually commences in middle life. Aortic incompetence may be due to, (a) secondary involvement of the valve by the disease-process; or (b) dilatation of the aortic ring, the result of dilatation of the aorta just above the valve, *i.e.* relative aortic incompetence; or (c) both. (3) Primary chronic endocarditis, more particularly when the affection occurs at a later period of life.

Relative incompetence of the aortic valve is sometimes due to general dilatation of the aorta just above the ring caused by atheroma. Aortic incompetence is the most frequent chronic valvular affection due to injury, and may follow sudden physical overstrain, causing a rupture of a valve segment. The condition is extremely rarely of congenital origin.

Symptoms.—For the symptoms of syphilitic aortitis, see pp. 947–949.

When aortic incompetence is the result of a previous attack of acute endocarditis, the subjective symptoms may be considerably, or even long, delayed.

Shortness of breath on exertion is perhaps the most frequent symptom. Symptoms of cerebral anæmia (see page 826) are much more apt to occur early than in mitral disease, while præcordial pain is more frequent, and angina pectoris much more likely. The patient may complain of palpitation, there may be a sensation of beating in the head, and nose bleeding is not a rare occurrence. The face is usually pallid and anxious, although in some cases the colour is flushed.

The symptoms of relative mitral incompetence may supervene.

The typical pulse is very characteristic, and is called the collapsing, the water-hammer, or Corrigan's pulse. Its character may be intensified by raising the arm above the head, and this method of examination should always be employed in suspected aortic regurgitation. The typical pulse is one of great amplitude, with an abrupt upstroke and a sudden fall. The tidal wave may be considerable, but is maintained only for a short period, the diastolic notch falls low on the downstroke, while the diastolic wave may be well marked, small, or altogether absent (Fig. 54). The artery is empty between the beats. When in addition to aortic incompetence stenosis is present, the characteristic pulse of the former will be modified by the latter

FIG. 54. Sphygmogram from a case of aortic incompetence.

condition; this is of great diagnostic importance in stenosis (Fig. 55). A high pulse-pressure is almost invariably a feature of aortic incompetence; the minimum pressure is sometimes considerably below and the maximum sometimes considerably above, the normal. A characteristic feature of aortic incompetence is exaggerated pulsation of the arteries; this may be especially noted in the carotid, temporal and brachial arteries. Increased pulsation of the retinal arteries is sometimes to be noted with the ophthalmoscope. The phenomenon of the capillary pulse may be observed, and pulsation in the superficial veins, especially in the veins of the back of the hand, when hanging down, is sometimes to be noted. In the opinion of some

FIG. 55.—Sphygmogram from a case of aortic stenosis and incompetence. The characteristic pulse of the latter condition is modified by the presence of stenosis.

writers, pulsation over the upper part of the præcordium, and in the second and third right intercostal spaces, is occasionally to be noted, even in the absence of dilatation of the aorta.

There are physical signs of hypertrophy of the left ventricle, which may even be very marked.

A diastolic thrill is rarely present; when it is, its maximum intensity is not infrequently at a lower level than the aortic area, and may even be felt towards the lower part of the sternum and in the neighbourhood of the apex-beat. A diastolic murmur is audible. It may replace or merely accompany the second sound, and it may continue for a variable distance into the long pause, diminishing in loudness. Its point of maximum intensity is very variable, the typical position being over the inner end of the second right intercostal cartilage. Frequently, however, it is in the second left space, or immediately over the sternum. More rarely it is at a lower level

than this, approaching even that of the apex-beat, and in my experience more often nearer the left than the right border of the sternum. In the opinion of some, in the absence of dilatation of the aorta, the point of maximum intensity is more frequently to the left of the sternum; and when dilatation is present, it is more often to the right of the sternum. The murmur has a tendency to be propagated downwards towards the lower end of the sternum. It is often heard over a wide area, and is usually blowing, but may be musical, and more rarely rough. An aortic systolic bruit is usually also present. Most writers are of opinion that in certain cases of aortic incompetences a pre-systolic murmur is audible at the apex (Flint's murmur). A diastolic murmur may be audible in the carotid, brachial and femoral arteries; the last of these is referred to as the murmur of Duroziez.

Physical signs of dilatation of the aorta are sometimes also present.

For the results of X-Ray examination, see p. 902.

Later, the physical signs of relative mitral incompetence may be present.

Course.—The course of aortic incompetence is very uncertain. Gradual cardiac failure is the rule, but, on the other hand, death may occur suddenly, from syncope, angina pectoris or coronary occlusion.

Diagnosis.—For the diagnosis of syphilitic aortitis, see pp. 949, 950.

There is little or no difficulty in recognising aortic incompetence in the great majority of cases. The characteristic radial pulse, the high pulse-pressure, the greatly exaggerated pulsation of the arteries, the physical signs of hypertrophy of the left ventricle, the characteristic murmur, capillary pulsation, and, rarely, visible pulsation in the superficial veins, present a definite clinical picture with regard to the diagnosis of which there should be no mistake. It should be remembered, however, that the phenomenon of the capillary pulse and pulsation of the superficial veins are occasionally also seen in other conditions. The murmur of Duroziez is pathognomonic of the lesion. X-Ray examination may furnish valuable information with regard to both diagnosis and differential diagnosis.

When the point of the maximum intensity of the murmur is in the pulmonary area, the condition may be mistaken for pulmonary incompetence. In this event, the points which should be remembered in considering the differential diagnosis are that pulmonary incompetence occurs more frequently in early life, that the pulse is not collapsing in character, that there is an absence of greatly exaggerated pulsation of the arteries and of capillary pulsation, that there is evidence of hypertrophy of the right, and not of the left, ventricle, and that the accompanying murmur is very rarely propagated as far down as the apex of the heart, and is never audible over the carotid artery. Dyspnoea, cyanosis, and clubbing of the fingers are also more suggestive of pulmonary incompetence. Occasionally a diagnosis of mitral stenosis is made in cases of aortic incompetence, when the point of maximum intensity of the diastolic bruit—especially when the bruit is only audible towards the latter part of the long pause—is as low as, or lower than, half-way down the sternum and on the left side of the middle line, and especially so when it is near the apex-beat. The points of differential diagnosis are the following: In mitral stenosis the pulse is markedly different from that of aortic incompetence, and, further, there is an absence of greatly exaggerated pulsation of the arteries and of capillary pulsation, there is evidence of hypertrophy of the right, and not of the left, ventricle, the murmur is

harsher in character, the first sound is short, sharp and clear, and the area of the thrill and murmur is usually very limited.

Prognosis.—The prognosis of aortic incompetence is usually serious. Sudden death is more frequent than in any other form of chronic valvular disease, and may occur even when there are little or no indications of cardiac failure.

In attempting to form a prognosis, we should endeavour, among other inquiries, to ascertain the ætiology, the degree of the lesion, whether it is stationary or progressive, and the condition of the myocardium, the aorta and the coronary arteries, and whether the patient is subject to syncopal attacks and attacks of angina pectoris. The ætiology is very important. When the lesion is the result of a previous attack of acute endocarditis, the prognosis is much more favourable than when due to other causes ; indeed, if there be no indications of cardiac failure, and if the rate and character of the pulse, the pulse-pressure, and the size of the heart, exhibit little or no alteration, and if the murmur merely accompanies the second sound, the patient may live to an advanced age. When it is due to primary chronic endocarditis, the prognosis is less favourable, as the lesion is more likely to be progressive, and to be associated with chronic myocardial disease, and atheroma of the aorta and even of the coronary arteries. If syphilis is responsible for the lesion, the outlook is much worse. When aortic incompetence is the result of rupture of a cusp, the prognosis is still more grave, and a fatal termination may rapidly supervene. The degree of the lesion is also very important ; in which regard, the degree of modification of the pulse and of the blood-pressure, and the size of the heart are of special significance. Syncopal attacks and attacks of angina pectoris are of grave omen. ✓

PULMONARY STENOSIS

Pulmonary stenosis may be due to a lesion of the cusps, or of the conus arteriosus.

Ætiology.—The disease is almost always congenital ; indeed, it is perhaps the most common congenital cardiac affection. When it occurs as an acquired condition, in the opinion of some, it may be due to a previous attack of acute endocarditis, and when this is so, it is usually associated with tricuspid stenosis. It has been supposed that the condition sometimes results from pressure of an aortic aneurysm. In some cases the ætiology is obscure.

Symptoms.—The symptoms of the congenital form of the disease will be discussed under Congenital Heart Disease. In the acquired form, the degree of dyspnœa is, as a rule, not great, and some authorities are of opinion that there is little tendency to cyanosis in these cases ; similarly, there is a difference of opinion as to the existence of clubbing of the fingers and toes. The tendency to chronic venous stasis is not great.

Prognosis and Treatment.—These will be discussed later.

PULMONARY INCOMPETENCE

Pulmonary incompetence is the rarest of all valvular lesions.

Ætiology.—The condition is found more commonly in early life, and in

about equal frequency in both sexes. It occurs occasionally in congenital heart disease, when it is often the result of superadded septic endocarditis, but sometimes it is due to dilatation of the pulmonary artery. Pulmonary atheroma may cause pulmonary incompetence, either from dilatation of the pulmonary artery, or involvement of the cusps, or both. Dilatation of the pulmonary artery, either with or without atheroma, may be the result of increased pressure in the pulmonary circulation, especially in mitral stenosis and chronic pulmonary disease.

Symptoms.—There may be a certain degree of cyanosis and dyspnoea, usually only present on exertion, while not infrequently there is also clubbing of the fingers. At a late stage cyanosis becomes marked, dyspnoea occurs apart from exertion, there may be anasarca of the dependent parts, catarrh of the mucous membranes, enlargement of the solid abdominal viscera, transudation of fluid into the serous sacs, the urine may become scanty and high-coloured, while affections of the respiratory system are especially apt to occur. There may be evidence of chronic venous congestion and oedema of the lungs, particularly of the bases, and more rarely pulmonary infarction occurs.

The pulse may be small and feeble, and the blood-pressure is, as a rule, subnormal. There may be physical signs of hypertrophy and dilatation of the right ventricle and, later, of the right auricle, described elsewhere. Distension or pulsation of the jugular veins may be present. Rarely a diastolic thrill is present, having its point of maximum intensity over the pulmonary area. On auscultation, a diastolic murmur, with its point of maximum intensity in the pulmonary area, usually soft and blowing in character, is audible, sometimes over a considerable area, its direction of selective propagation being downwards towards the lower end of the sternum.

Diagnosis.—The diagnosis of pulmonary incompetence is frequently a matter of considerable difficulty. The lesion with which it is most likely to be confounded is aortic incompetence, because the point of maximum intensity of the thrill and murmur of the latter is not infrequently to the left of the sternum. The differential diagnosis between these two conditions has been discussed under aortic incompetence. The symptoms of pulmonary incompetence and patent ductus arteriosus resemble each other; in the case of the latter the murmur occupies both systole and diastole.

Prognosis.—When due to organic disease and when unaccompanied by any other valvular lesion, the prognosis in pulmonary incompetence may not be unfavourable; instances, indeed, have been recorded in which life has been prolonged almost to the normal span. In *relative* incompetence, on the other hand, the prognosis is usually very serious. Death in either case may result from right-sided cardiac failure, bronchitis or broncho-pneumonia, or pulmonary tuberculosis.

TRICUSPID STENOSIS

Ætiology.—Tricuspid stenosis occurs much more commonly in males than in females—in a proportion of at least three to one. The acquired form is the more common. It is usually associated with mitral stenosis, and is due to a previous attack of acute endocarditis caused by rheumatism, chorea, or more probably one of the acute specific fevers. In many cases, however, the cause cannot be ascertained. The congenital form is very rare, except in infants dying soon after birth.

Symptoms.—In the acquired form of the disease, cyanosis is the most conspicuous symptom, and may be very marked; dyspnoea is less evident, and may be only present on exertion. The skin temperature of the extremities is often subnormal, and the individual complains of feeling cold and is very susceptible to any fall of temperature. The cerebral functions are not infrequently affected. Oedema about the ankles is sometimes present, and at a later stage may become general, together with hepatic enlargement and pulsation, ascites, splenic enlargement, and scanty high-coloured urine.

The radial pulse may be of increased rate and smaller volume. The apex-beat may be displaced to the left, and there is usually distension, and it may be pulsation, of the jugular veins. There may be a presystolic, or more rarely a diastolic thrill, with its point of maximum intensity in the tricuspid region. On percussion, the right border of the heart is found to be displaced to the right, on account of enlargement of the right auricle, and the left border may be found to be displaced outwards. On auscultation, a murmur may be present, limited in extent, having its point of maximum intensity in the tricuspid area. It is usually presystolic, but may be diastolic. The presystolic murmur is almost invariably rough; it may even be harsh and vibratory in character. The diastolic murmur, on the other hand, is usually soft and blowing. In some cases no murmur of any kind is audible. In certain instances, some writers have recorded a short, sharp first sound in the tricuspid area. When pulsation of the liver is present, the pulsation is of the auricular and not of the ventricular type.

Diagnosis.—In by no means an inconsiderable proportion of cases of tricuspid stenosis the lesion is entirely overlooked. In the opinion of Mackenzie, we may infer that tricuspid stenosis in all probability exists when pulsation of the liver is found to be auricular in type.

The differential diagnosis of tricuspid and mitral stenosis is often a matter of great difficulty. The early appearance of marked cyanosis and of extensive dropsy are features in favour of the existence of the former lesion. When the point of maximum intensity of the murmur is strictly in the tricuspid area, we can be fairly certain of the diagnosis. It should be remembered that both lesions may be present; in this case a murmur with its point of maximum intensity midway between the tricuspid and mitral areas, or two murmurs with separate points of maximum intensity, may be detected. The value of the auricular type of hepatic pulsation has been noted.

Prognosis.—The prognosis in this affection is by no means easy. It largely depends upon whether mitral stenosis also exists, and if present, in what degree; if this be present, the prognosis is usually very unfavourable.

TRICUSPID INCOMPETENCE

Ætiology.—It should be noted at the outset that the reflux of a certain amount of blood through the tricuspid orifice may occur under physiological conditions. In severe muscular exertion, for example, where the intracardiac pressure on the right side of the heart is excessive, a natural function of the tricuspid valve is to provide for a certain amount of regurgitation, and thus afford relief to the temporary embarrassment due to distension of the right ventricle.

Pathological tricuspid incompetence is rarely congenital, and when it

is, is usually associated with pulmonary stenosis. Apart from those of congenital origin, there are two classes of cases—(1) Those in which the incompetence of the valve is primary, that is, due to a lesion of the cusps themselves—a rare condition ; and (2) cases of *relative* tricuspid incompetence, in which the cusps are normal, the incompetence being due to dilatation of the right ventricle. The latter constitute the great majority of cases.

With regard to the first group, the lesion may be the result of a previous attack of acute endocarditis, in which case the tricuspid incompetence rarely occurs alone ; there is usually tricuspid stenosis, and also some other valvular lesion, more especially some structural alteration of the mitral cusps. Infective endocarditis may affect the tricuspid valve alone.

Relative incompetence is always consequent on some other condition. It may result from affections which cause increased pressure in the pulmonary circulation, such as mitral disease and chronic pulmonary disease, pulmonary stenosis and incompetence, acute febrile affections, acute myocarditis, chronic myocardial disease and anæmias.

Symptoms.—There is always a tendency to cyanosis, which may be marked, while dyspnoea on exertion is almost always present. Headache and giddiness are of common occurrence, while insomnia and other cerebral symptoms may occur. Digestive disturbances and even jaundice may be present, and in rare instances hæmatemesis and melæna. Œdema about the ankles may also be noted. These patients are very liable to attacks of bronchial catarrh, while, later, there may be evidence of chronic venous congestion and œdema of the lungs, hæmoptysis, and hydro-thorax, the latter being more likely to occur in tricuspid incompetence than in affections of the left side of the heart. Hepatic enlargement and pulsation, ascites, general anasarca, and scanty and high-coloured urine may be also present in the later stages of the disease.

The pulse is usually small. There may be physical signs of hypertrophy and dilatation of the right ventricle and right auricle (see elsewhere). Occasionally a systolic thrill is present in the tricuspid area. Visible distension and pulsation of the jugular veins may exist. If the vein be emptied from below by means of the finger, and its upper extremity kept closed by pressure, it rapidly fills from below. The pulsation of the jugular vein is usually of the ventricular form, but occasionally is of the auricular type. The liver may be enlarged and pulsating, the pulsation being strictly systolic in time—unless tricuspid stenosis also exists. On auscultation, a murmur, systolic in time, having its point of maximum intensity in the tricuspid area, and usually soft and blowing in character, is usually, but by no means always, audible. It is conducted towards the right, but, as a rule, its area of conduction is slight. The pulmonary second sound is diminished in cases of tricuspid incompetence uncomplicated by a mitral or pulmonary lesion.

As relative incompetence of the tricuspid valve is always consequent upon some other condition, the physical signs of the primary affection are to be noted.

Diagnosis.—When, after being emptied from below by means of the finger, the jugular vein rapidly fills from below, and when pulsation of the liver occurring synchronously with the apex-beat, evidence of enlargement of the right side of the heart, a soft blowing systolic murmur having its

point of maximum intensity in the tricuspid area, and diminution of the pulmonary second sound are also present, no doubt need arise regarding the diagnosis. In marked tricuspid incompetence the murmur may be absent, in which case a positive diagnosis can be made when the first three signs mentioned are present; most writers, indeed, agree that the first sign is sufficient for a diagnosis. In slight cases, a systolic murmur audible in the tricuspid area may be the only existing physical sign; but we should make certain the murmur is not propagated from any other area.

Prognosis.—The prognosis of tricuspid incompetence depends upon the cause and associated condition. When the affection is due to organic disease, the outlook is serious.

With regard to relative tricuspid incompetence, when this is the result of left-sided valvular disease it is usually serious; it may be the precursor of a fatal termination in the near future. When, on the other hand, it is due to chronic pulmonary affections, acute febrile affections or anæmia, the prognosis may be good.

TREATMENT OF CHRONIC VALVULAR DISEASE

The ætiology should be reviewed. In this connection, the treatment of syphilitic aortitis is described on pp. 951, 952. Explicit and detailed instructions with regard to his manner of life should invariably be given to the patient. The importance of always living within the limits of the heart's strength, and avoidance of sudden and violent effort, should be specially emphasised in aortic disease. The question of oral sepsis is an important one, and this should receive attention, with the object of diminishing the risk of infective endocarditis. In mitral disease the patient is liable to attacks of bronchitis and broncho-pneumonia, and in both mitral and aortic disease in children and young adults there is a liability to recurrent acute and subacute rheumatic attacks; preventive measures should therefore be adopted, and if, notwithstanding an attack of either occur, it should be immediately and adequately treated.

The various measures which may be applicable to any form of heart disease, described on pp. 832–847, should be considered in detail.

The Surgical Treatment of Mitral Stenosis.—Samways, in 1898, anticipated that, with the progress of surgery, some of the most severe cases of mitral stenosis might be relieved by "slightly notching the mitral orifice." Lauder Brunton, in 1902, suggested elongating the natural opening, or cutting through the valves at the middle at right angles to the normal opening. Doyen, later, operated on a case, but the patient died very shortly afterwards. Cutler and Levine, in 1923, published the case of a girl, aged 12, on whom they had operated. A valvulotome was plunged into the left ventricle an inch from the apex, and pushed upwards for $2\frac{1}{2}$ inches, until it had reached as far as what was thought to be the mitral orifice. They believed that the aortic leaflet was cut. The patient recovered from the operation, but it was too early to form an opinion as to any benefit that might have accrued. They were of opinion that the mitral diastolic thrill and murmur had diminished in intensity, while the systolic murmur had increased. A pericardial to-and-fro friction had developed, and had gradually

grown fainter. Numerous experiments have also been made by Cushing and others. Goodall and Rogers discussed the subject in a paper, and expressed the opinion that the auricular route is better than the ventricular, as an instrument passed from the ventricle into the auricle is more likely to injure the latter than it is to damage the ventricle if passed in the opposite direction. The reasons for and against the ventricular and auricular routes were considered. The same writers published another paper on the subject, almost identical with the former. Souttar published a case in which he used the auricular approach, and dilated the valve with the finger. The patient was a girl, of 15 years of age. She recovered, and, although still breathless, was much improved. Jarotzky, while not putting the operation into practice, suggested that, in cases of mitral stenosis where the general condition is good, but in which the patients from time to time suffer from the formation of infarcts, an opening should be made between the two auricles by passing an instrument through the jugular vein and the superior vena cava directly into the right auricle.

FREDERICK W. PRICE.

DISEASES OF THE MYOCARDIUM

Affections of the myocardium are of profound importance. It has been pointed out that valvular defects, diseased conditions of the blood-vessels, and disturbances of the cardiac mechanism, should be regarded from the point of view of their relation to the myocardium, and not so much as specific affections in themselves. It has also been noted that, along with valvular lesions, coincident changes in the cardiac musculature, the aorta, or coronary arteries are, as a rule, present. We are, however, now concerned with affections of the myocardium occurring independently of valvular disease.

MYOCARDITIS

Varieties.—The varieties which may be met with are—(1) Acute, (a) simple, and (b) suppurative; and (2) chronic. (3) Tuberculous myocarditis.

ACUTE MYOCARDITIS

Strictly speaking, by this term is meant acute inflammation of the heart-muscle, but it is generally used to include also morbid changes of a degenerative nature, and I shall so use it.

Suppurative myocarditis is of uncommon occurrence. It is usually the result of pyæmia or infective endocarditis. In this condition large abscesses in the myocardium are rare; they may perforate into the ventricle or pericardium. Minute abscesses, on the other hand, generally at the base of the left ventricle, are not rare.

Chronic Myocarditis will be discussed under Chronic Myocardial Disease.

Tuberculous myocarditis is almost always the result of extension from a tuberculous pericarditis. It usually takes the form of miliary tubercles.

ACUTE SIMPLE MYOCARDITIS

Ætiology.—Acute simple myocarditis is most common in childhood and adolescence. Acute and subacute rheumatism, in one of its forms (see p. 886), accounts for the great majority of cases. It may be caused by scarlet fever, diphtheria, influenza, small-pox and other acute infective diseases, and possibly thyrotoxicosis. Some degree of myocarditis is almost always present with pericarditis, and probably also with endocarditis.

Pathology.—Acute simple myocarditis may be general, or limited to one or more portions of the cardiac wall. Acute degenerative processes, especially fatty degeneration, of the muscle-fibres are usually found. The interstitial connective tissue, on the other hand, may show little or no change, or may exhibit considerable cellular infiltration. In rheumatic myocarditis what are called *Aschoff's nodes*, described on p. 329, are often to be found, and in the opinion of many are pathognomonic of the rheumatic infection. Later, they become converted into fibrous tissue. In diphtheria there is

FIG. 56.—Tracing of the radial pulse, from a child suffering from croupous pneumonia, showing extra-systoles. Note the slight pulsus alternans following the extra-systoles.

usually a diffuse acute degenerative process. Some writers recognise two forms of myocarditis, the parenchymatous and the interstitial; in most cases, however, both the parenchyma and interstitial tissue are affected. Dilatation of one or more chambers of the heart usually supervenes.

Acute simple myocarditis may be followed by—(1) Complete resolution, in which no permanent changes supervene; or (2) the formation of fibrous tissue, which tends to contract as life advances, and which may occur in limited areas or may involve the whole myocardium. The latter condition is known as chronic myocarditis.

Symptoms.—In the first place, the reader is referred to the remarks on p. 886.

The clinical picture of acute myocarditis varies considerably in different cases; not infrequently it is indefinite, and, indeed, in rare instances the condition may remain latent during its whole course and is only discovered post mortem, death being due to the severity of the primary illness.

The onset may be insidious, or there may be a definite change in the clinical picture of the causative disease. If pyrexia be already present, there may be a further rise of temperature, or if there has been no pre-existing pyrexia it may develop; it may be signalled by a rigor, and be slight or considerable

in degree. The patient may complain of shortness of breath, palpitation, præcordial discomfort or pain. There may be great prostration, and syncopal attacks may occur if the affection is severe. Cheyne-Stokes respiration may be occasionally noted. Vomiting not infrequently occurs and, indeed, may be the first symptom. Indications of severe cardiac failure may be met with. As the illness progresses, the patient may sink low in bed, complain of headache, with restlessness, insomnia, convulsions, muttering delirium, stupor, and even coma. The severity of the subjective symptoms may be out of all proportion to the physical signs.

The pulse is usually increased in frequency, but even bradycardia may be present. It is usually feeble and soft. In some cases there is irregularity of rhythm, due to extra-systole (Fig. 56), or partial heart-block (Fig. 57), or auricular fibrillation; exceptionally, complete heart-block is present. The apex-beat may be displaced outwards, and may be diffuse and diminished in force, and even abolished in severe myocarditis. The area of cardiac impairment is usually increased transversely, both to the left and right, as

FIG. 57.—Simultaneous tracings of the jugular and radial pulses, from a case of acute myocarditis occurring during diphtheria, showing partial heart-block. Every third stimulus from the auricle fails to reach the ventricle.

the result of dilatation, which may sometimes come on rapidly and even early in the disease. The first sound is diminished, and may be short, sharp and clear. Sometimes tic-tac rhythm, or gallop rhythm, may be present. The second sound over the pulmonary area is sometimes accentuated, and occasionally reduplicated. A systolic murmur is not infrequently heard over the mitral and sometimes over the tricuspid area, due to functional inefficiency of the valves; a systolic bruit is perhaps more commonly noted over the base of the heart.

In diphtherial and influenzal myocarditis, the symptoms may appear either during the febrile stage of the disease or during convalescence; this applies also, but less frequently, when some other cause of myocarditis is present. When the symptoms appear during convalescence, they are not so acute or so severe. Among them may be noted anorexia, languor and pallor; dyspnoea, fatigue, præcordial discomfort or pain, and possibly syncopal attacks on exertion; tachycardia, subnormal blood-pressure, an enfeebled cardiac impulse, evidence of slight cardiac dilatation, a modified first sound at the apex, an accentuated pulmonary second sound, and sometimes a mitral systolic bruit.

The diphtherial form of myocarditis may be mild or severe. There may be bradycardia; in the severe form there is usually albuminuria, and a fatal termination may take place rapidly from cardiac failure. A severe form of myocarditis has been met with in septicæmia and in severe cases of enteric fever.

Diagnosis.—The diagnosis of acute simple myocarditis is often exceedingly difficult. The recognition of a mild form occurring during or after the febrile stage of any acute infective disease may be arrived at from a consideration of the symptoms already enumerated. The presence of severe myocarditis may be presumed when there are indications of severe cardiac failure coming on rapidly during the course of an acute infective disease, and out of proportion to the severity of the latter, an increase of cardiac impairment being perhaps especially significant. I would emphasise the importance of being on the look-out for the occurrence of partial heart-block during the course of an acute infective disease, for it is a sign, and may be the only sign, of myocardial damage. It may be necessary in any given case to differentiate acute myocarditis from acute endocarditis, and this is often a matter of extreme difficulty, for it should be remembered that both conditions may co-exist, and a mitral systolic murmur may be due to either (see also p. 889).

Prognosis.—The prognosis of the severer forms of acute myocarditis is very grave, the mortality being high; the course of the disease is rapid, a fatal termination occurring usually within a week, and in some cases even within 24 hours, although life may be prolonged for several weeks. Death is usually due to cardiac failure, which may occur suddenly; in rare instances to rupture of the wall of the heart. Sudden death is particularly prone to occur in diphtherial myocarditis, and may take place even when the patient is considered convalescent. Among the symptoms of bad omen are marked pallor, restlessness, syncopal attacks, vomiting, a greatly accelerated pulse of low tension, bradycardia, and a modification of the heart-sounds resembling the foetal type. In the milder forms, however, recovery is the rule if early and adequate therapeutic measures be adopted.

Treatment.—The treatment of acute myocarditis is of great importance, and is the same as that of acute simple endocarditis.

DISEASES OF THE CORONARY ARTERIES

Before dealing with the various forms of chronic myocardial disease, it may be advisable to mention a few points regarding diseases of the coronary arteries, as they bear an important causal relation to some of them, coronary disease being usually accompanied by morbid changes in the cardiac musculature.

Atheroma and syphilitic mesaortitis of the ascending aorta may give rise to narrowing or complete occlusion of the orifice of one or both of the coronary arteries. Atheroma and, in the opinion of many, rarely syphilitic arteritis may also affect the coronary arteries themselves, resulting in narrowing or occlusion of the vessels. Occlusion is almost invariably due to thrombosis, but is rarely the result of a progressive narrowing of the lumen of the vessel caused by the disease-process itself.

Complete occlusion of the orifice of one of the coronary arteries, or of a coronary artery itself, or one of its main branches, is much more frequently the result of atheroma than of arteritis. It is rarely due to embolism, usually intra-cardiac in origin. The left coronary artery, or one of its main branches, is much more commonly occluded than the right. The descending branch of the left coronary artery is the most frequently affected.

If the orifice of one of the coronary arteries, or of a coronary artery itself, or of one of its main branches, be completely and abruptly closed as the result of one of the causes mentioned, sudden death, without the occurrence of structural changes, may occur; or acute infarction may ensue. In those cases in which occlusion of the orifice of one of the coronary arteries, or of a coronary artery itself, or of one of its branches, is gradual, or only partial, almost invariably either, ischemic fibrosis of the myocardium, or, less frequently, fatty degeneration, or both, occur.

CHRONIC MYOCARDIAL DISEASE

Of the various forms of chronic myocardial disease, the most common are chronic myocarditis, fibrosis of the myocardium, fatty degeneration, and fatty infiltration.

CHRONIC MYOCARDITIS ; FIBROSIS OF THE MYOCARDIUM

By chronic myocarditis is meant a chronic inflammatory affection of the heart muscle. It is to be noted, however, that this ultimately results in the formation of fibrous tissue, *i.e.* fibrosis of the myocardium, in which the heart muscle is replaced, in varying degree, by fibrous tissue.

Fibrosis of the myocardium is also termed chronic interstitial myocarditis, fibrous myocarditis, cardio-sclerosis, or fibroid degeneration of the myocardium.

Ætiology.—Chronic myocarditis may be the result of a previous attack of acute endocarditis, or associated with chronic endocarditis or chronic adhesive pericarditis. With regard to the ætiology of fibrosis of the myocardium, heredity is a factor. The condition is more common in males, and during or after middle life. Prolonged muscular or mental stress or strain, over-indulgence in food or drink, focal sepsis, the various forms of chronic rheumatism and gout, chronic metallic poisoning—particularly that due to lead, hypertension, and chronic renal disease are among the most common causes. It is possible that the last has no direct relation, the associated hypertension being the causal factor. Disease of the ascending part of the aorta and of the coronary arteries (see above) constitutes the cause of a large proportion of cases of myocardial fibrosis, and there may be co-existing fatty degeneration. Syphilis is an important cause of fibrosis of the myocardium. In such cases, the fibrosis may be the result of narrowing of one or both of the orifices of the coronary arteries, or rarely of the coronary arteries themselves, *i.e.* ischemic fibrosis; or of a pre-existing chronic diffuse inflammation of the myocardium; or, rarely, of gummata. There is a marked divergence of opinion regarding the relative frequency of the first and second. In the opinion of some, notably Warthin, syphilis very frequently causes chronic

diffuse inflammation of the myocardium, ultimately resulting in fibrosis. The general consensus of opinion, with which I agree, however, is that, so far as present evidence is concerned, the former is of infrequent occurrence, and that the fibrosis is of ischæmic origin. Chronic venous congestion of the myocardium, due to chronic valvular disease or chronic pulmonary disease, and an old infarct are other causes of myocardial fibrosis.

✓ **Pathology.**—The morbid affection may be general or local in its distribution, the latter being usually due to coronary disease. When the affection follows acute myocarditis, a more or less diffuse fibrosis, usually most marked beneath the pericardium and endocardium, is found. In both forms the auricles are little, if at all, affected, and the left side of the heart is much more commonly affected than the right, especially in the neighbourhood of the apex and the lower part of the interventricular septum. When the condition is the result of chronic venous congestion, however, it is more in evidence on the right side of the heart. There is an increase in the thickness of the cardiac wall—the so-called false hypertrophy—and ultimately dilatation occurs. White masses of fibrous tissue, varying in size from that of a pea to a five-shilling piece or even larger, and irregular in shape, are to be observed replacing portions of the cardiac wall or interventricular septum. When the condition has continued for some time and the increase of fibrous tissue is extreme, the affected muscle-fibres may be entirely replaced by dense scar-like tissue.

See also pathology of causative condition.

Symptoms.—The clinical picture varies considerably in different cases. In rare instances, the disease is latent until a fatal termination occurs, while if the morbid condition be general or excessive, the malady may be difficult to distinguish from fatty degeneration.

The onset of the symptoms is usually gradual, and the clinical features are those of chronic cardiac failure. The most common symptoms are progressive dyspnoea, and it may be, slight cyanosis of the face, and discomfort or pain in the præcordium on exertion. There may also be slight œdema about the ankles, especially at night. Cerebral symptoms, described on p. 826, are not infrequent. There may be a sensation of fullness and throbbing in the head. Angina pectoris is not of uncommon occurrence, the patient may suffer from attacks of cardiac asthma, especially at night, and Cheyne-Stokes respiration sometimes, and Adams-Stokes syndrome occasionally occurs. Indications of failure of the right side of the heart may supervene. Ultimately the patient is apt to suffer from severe dyspnoea on the slightest exertion, orthopnoea, and distressing cardiac asthma, and the quantity of urine steadily diminishes and œdema increases.

The pulse may be increased in frequency, or there may even be bradycardia. Its character varies considerably: it is usually fuller than normal, with increased pressure, although the latter is not pronounced unless there is co-existing hypertension, or chronic renal disease. When cardiac failure is present, however, not infrequently the complete irregularity associated with auricular fibrillation, or it may be heart-block, is present. The apex-beat is usually displaced downwards and to the left, its area and force are often, if not usually, increased, the area, however, being proportionately greater and the force of the apex-beat proportionately less than in pure hypertrophy.

The area of cardiac impairment is increased in all directions. On auscultation, at the apex the first sound is prolonged and muffled, with often a soft murmur; while at the base it is often diminished, and may be scarcely audible or even absent. The second sound in the aortic area may be reduplicated; when due to mitral disease, however, that in the pulmonary area may be accentuated. A tricuspid systolic bruit is sometimes present. Sometimes gallop rhythm, or in rapidly acting hearts tic-tac rhythm, is to be noted. Not infrequently there are indications of general atheroma.

Diagnosis.—A diagnosis of fibrosis of the myocardium may be exceedingly difficult. Usually, however, it is possible to make a definite diagnosis as the result of a consideration of the clinical picture described. A combination of the existence of subjective symptoms on physical exertion, enlargement of the heart, and an absence of a valvular lesion are of especial value. The differential diagnosis from fatty degeneration is described on p. 927. It is necessary to distinguish myocardial fibrosis in which relative mitral incompetence has supervened from organic mitral incompetence, which may be very difficult. In the former case there is no history of valvular disease, the subjective symptoms are frequently out of proportion to the physical signs, and angina pectoris and syncopal attacks are of more frequent occurrence.

Prognosis.—The prognosis of the affection closely resembles that of fatty degeneration. Here also the duration of life may vary from a few months to many years. In estimating the prognosis, the various points described on pp. 829–832 should be taken into consideration. Of special significance are the ætiology, the size of the heart, the cardiac rhythm, the question of cardiac failure, the existence or otherwise of angina pectoris, syncopal attacks, pulsus alternans, and of arterial and renal disease.

The most frequent cause of death is congestive heart failure. Sudden death may be due to angina pectoris, rupture of the heart, or other causes.

Treatment.—The ætiology should be reviewed with the object of treating the underlying cause, and the same applies to any co-existing associated morbid condition, such as obesity.

It is of the greatest importance that the patient should curtail his physical and mental activities so as not to exceed the limited strength of his heart. Regulated exercise in the open-air, provided such stops short of inducing abnormal subjective symptoms, is indicated. Quiet walking on the level, or slow walking up an incline, cycling on the level in the absence of a strong head-wind, riding a non-pulling horse, or golf may be allowed in suitable cases. High altitudes should be avoided. The various therapeutic measures described on pp. 832–847 should be considered carefully and in detail. ✓

FATTY DEGENERATION

In fatty degeneration the muscle-fibres are more or less replaced by ^{fat.}

Ætiology.—Heredity is certainly a factor, and the condition is more common in males. It is far more frequent during middle life and in the

elderly. The condition is found in altered states of the blood, such as per-
 icious anæmia, leukæmia, purpura, and scurvy; chemical and metallic
 poisoning, as, for example, by phosphorus, arsenic, antimony, alcohol,
 chloroform, and lead; the acute infective fevers, such as enteric fever, typhus,
 diphtheria, and small-pox; long-standing valvular disease and chronic pul-
 monary disease; diseases of the coronary arteries; and as a sequel of fatty
 infiltration.

Pathology.—The affection may be general or local in its distribution,
 the latter being the more common. In both cases, but especially in the local
 form, the ventricles are affected to a greater degree than the auricles, and
 the left ventricle than the right, except in chronic venous congestion of the
 lungs, and the muscoli papillares and the muscle beneath the endocardium
 are principally involved. The heart may or may not be enlarged; indeed,
 in pure degeneration it may be even smaller than normal. In this connection
 it may be stated that fatty degeneration may accompany or succeed dilatation
 or hypertrophy, while, on the other hand, dilatation may follow degeneration.
 The organ is softer in consistence and flabby, and is more easily torn. The
 colour may be uniformly pale yellowish, or buff, or light yellowish brown—
 the so-called “faded-leaf” colour. The condition may, however, occur in
 patches, resulting in a streaked or mottled appearance as a whole, which has
 been likened to that of the breast of a thrush—“thrush’s-breast,” or to that
 of the fur of a tabby cat—“tabby cat striation.” On microscopic examina-
 tion of a section which has been stained with osmic acid, the small fat globules
 are seen inside the muscle-fibres, their envelopes being blackened by the
 acid.

Symptoms.—The clinical picture is usually indefinite, and rarely the
 disease is latent until a fatal termination occurs.

The most common subjective symptoms are dyspnœa, together with some
 degree of cyanosis of the face, and perhaps giddiness and acceleration of the
 pulse-rate on exertion, and debility and general lassitude. In some cases
 there is discomfort or pain in the præcordium on exertion, but cardiac pain
 is usually not a prominent feature of the disease, except in those cases in
 which angina pectoris accompanies it, which is by no means uncommon.
 Cerebral symptoms, described on pp. 826, 827, are often present and of great
 diagnostic importance. The digestive functions are usually impaired, as
 evidenced by anorexia, drowsiness after meals, atonic dyspepsia, and torpidity
 of the functions of the liver and bowel. There is sometimes some œdema
 about the ankles, but general dropsy is rare, unless there is much cardiac
 dilatation. Occasionally Cheyne-Stokes respiration, usually not until an
 advanced stage of the disease, and generally occurring during sleep, is to be
 noted. It is possible that very rarely the Adams-Stokes syndrome may
 occur.

The countenance is not infrequently pale and waxy, but it may be ruddy
 or even cyanotic; cyanosis, however, is rarely seen unless there is much
 cardiac dilatation. Coldness of the extremities and a subnormal tempera-
 ture may be present. The urine is usually of low specific gravity, and not
 infrequently contains a trace of albumin and tube casts.

The pulse may be increased in frequency, especially in the more acute
 forms of the disease, or, on the other hand, there may even be bradycardia,
 even of marked degree, in the more chronic forms. The pulse is usually

small and ill-sustained, but may be full. Occasionally the complete irregularity associated with auricular fibrillation is present. The blood-pressure is usually subnormal. The apex-beat is either very weak, giving the impression to the hand of a short feeble tap, or may not be palpable. The area of cardiac impairment is generally enlarged, but usually not to any great extent. The first sound is usually diminished, and may be short, sharp and clear; at the advanced stage it may be almost or even inaudible at the apex, although faintly heard in the neighbourhood of the left border of the lower end of the sternum. In the case of rapidly acting hearts, the foetal type of cardiac action may be approximated. A mitral and tricuspid systolic murmur may be present, especially when the condition is due to altered states of the blood or acute infective fevers.

Diagnosis.—The diagnosis is often extremely difficult and, in the opinion of some, a positive diagnosis is not possible. The following points are of importance: a causative history or morbid affection; dyspnoea, cyanosis, and cerebral symptoms, especially syncopal attacks on exertion; the occurrence of angina pectoris; the physical signs described; and an absence of indications of chronic valvular disease.

In the opinion of some, the differential diagnosis between fatty degeneration and fibrosis of the myocardium is not possible, and it should be noted that they often occur in association. The existence of constant torpor, cerebral symptoms on exertion, and the occurrence of a fatal termination before indications of a failing right heart occur are more suggestive of fatty degeneration. Further, in myocardial fibrosis, the pulse is usually more frequent, stronger, and of normal or supernormal tension, the vessel wall is thickened, the enlargement of the area of cardiac impairment is usually greater, and the aortic second sound accentuated. It should, however, be borne in mind that fatty degeneration may supervene upon the hypertrophy of valvular disease. In the differential diagnosis from valvular disease with cardiac failure, the history may be helpful, as also the characteristic murmurs of the various forms of valvular disease. In mitral disease, for example, hypertrophy is more marked, and, if cardiac failure be present, the usual clinical picture is one of chronic venous stagnation—a condition which is comparatively rare in fatty degeneration—and the degree of cardiac dilatation is greater.

Prognosis.—Taking the cases as a whole, the prognosis of fatty degeneration is grave, as it is one of the commonest diseases in which sudden death occurs. The duration of life, however, may vary from a few months to many years. In considering the probable duration of life, among the points which should be considered are the following: When the affection supervenes upon fatty infiltration the patient may live for many years. In the acute forms, as, for example, when due to altered states of the blood, the immediate prognosis is grave, but the ultimate prognosis is not infrequently favourable; the outlook in diphtheritic cases is, however, uncertain. In the chronic forms the immediate prognosis is more favourable, but the ultimate prognosis is not so good; and yet even in these cases life may be prolonged for some years, if the patient be able to live a carefully regulated life.

A fatal termination may result from gradual or rapid cardiac failure, or from sudden death, the latter occurring perhaps in a majority of cases, and may be due to syncope, angina pectoris, or rupture of the heart.

Treatment.—The treatment of fatty degeneration is the same as that of chronic interstitial myocarditis.

FATTY INFILTRATION

Fatty infiltration consists in an excess of fat in those situations in which it is naturally found, and also in its deposit between the fasciculi of the cardiac musculature.

Ætiology.—Heredity is certainly a factor, and the condition is more common in males, and during or after middle life, being rare in early life, and comparatively rare before middle age. It is usually associated with general obesity, a generous appetite, and lack of exercise and fresh air. It is more especially found in connection with over-indulgence in carbohydrates, fats and alcohol, particularly malt liquors and sweet wines, and faulty metabolism is generally present. It is also apt to occur in individuals suffering from affections of the lungs which cause embarrassment of the pulmonary circulation, such as emphysema, cirrhosis and chronic fibroid tuberculosis.

Pathology.—The affection is chiefly distributed along the arterial branches, often causing atrophy of the muscle-fibres by compression. It is usually most marked over the right ventricle. The deposit of fat commences in the subepicardial fat, and may even extend to the subendocardial tissue. In some instances the atrophied muscle-fibres become the seat of true fatty degeneration, due to interference with their nutrition. In fatty infiltration, more or less dilatation of the cardiac chambers is usually present, and is often accompanied by hypertrophy.

Symptoms.—The patient is usually stout and flabby, and the subjective symptoms are those of an enfeebled circulation. Exertion is frequently accompanied by dyspnoea, a sense of oppression in the chest, and slight cyanosis, with a tendency to perspire easily; the association of cyanosis with dyspnoea on exertion is one of the most usual features of the affection. The patient is easily fatigued by physical or mental effort, and there may be giddiness or faintness. The digestive functions are, as a rule, little, if at all, impaired; on examination, however, there may be evidence of gastric dilatation and of hepatic enlargement. The functions of the nervous system are often affected; there is frequently impairment of memory, and not infrequently the patient is soporose, although, on the other hand, he may complain of insomnia. The urine may be large in quantity, pale in colour, and of low specific gravity. The characteristics of the pulse vary considerably; as a rule the rate is increased, it is weak, the vessel is empty, there is hypotension, and the vessel wall is not thickened. On the other hand, the vessel may be full, the blood-pressure above the normal, and the wall thickened. The cardiac impulse is usually feeble, unless hypertrophy is also present. The area of cardiac impairment is generally increased, as the result of dilatation or hypertrophy. The heart-sounds, especially the first, are found to be weak, low in tone and muffled; indeed, in the advanced stage the first sound may be almost inaudible; this may be due not only to an enfeebled left ventricle, but also to the unusual thickness of the thoracic parietes in these cases. Murmurs are usually not present, but a soft mitral or tricuspid bruit may be audible, owing to cardiac dilatation.

Later on, there may be indications of a more severe degree of cardiac failure.

Diagnosis.—Fatty infiltration may be diagnosed from the indications of an enfeebled circulation, together with evidence of weakness of the cardiac impulse and sounds, occurring in a person who is the victim of obesity.

Prognosis.—If appropriate therapeutic measures be carried out, the prognosis is usually favourable; otherwise the condition is apt to be progressive. As has been already noted, if fatty infiltration persist for some time, true degeneration is apt to arise.

Treatment.—If general obesity is present, it should be treated (see pp. 455, 456). Regulated exercise in the open air is valuable, and systematic and graduated exercises, and massage (see p. 834) may be tried. Systematic elimination, by means of purgatives, Turkish baths, or a visit to some spa, is sometimes helpful.

HYPERTROPHY OF THE HEART

In cardiac hypertrophy there is an increase in the thickness of the walls of one or more of the cavities of the heart, due to an increase in the actual size, and possibly also in the number, of the muscle-fibres. The hypertrophy may include the *musculi papillares*, *columnæ carneæ*, and *musculi pectinati*.

It is customary to divide hypertrophy of the heart into three kinds, namely—(1) The concentric, in which with the increased thickness of the walls the cavities are diminished in size; (2) the simple, in which the cavities are normal in size; and (3) the excentric type, in which the cavities are increased in size—in other words, there is hypertrophy with dilatation. In the opinion of some, the concentric variety only exists as a post-mortem change.

Ætiology.—The ætiology of hypertrophy of the heart is the same as that of arterial hypertrophy (see pp. 1015, 1016); and hypertension, chronic valvular disease, chronic adhesive pericarditis, congenital heart disease, chronic interstitial myocarditis—so-called false hypertrophy, and chronic affections of the lungs or bronchi.

Pathology.—Hypertrophy of the heart may be general or local. In the former, all the chambers of the heart are involved. The ventricles are more affected than the auricles, for the walls of the latter contain more fibrous tissue. When the condition is local, which is much the more common, while all the chambers are not affected, there is, as a rule, hypertrophy of more than one, though in varying degree. The following is the comparative order of frequency: left ventricle, right ventricle, left auricle, right auricle. When the left ventricle is affected, the apex of the heart is accentuated, and the whole organ is elongated and rather conical in form. When the right ventricle, on the other hand, is concerned, the apex is less pronounced, and the whole organ broader and somewhat quadrate in form. The excentric variety of hypertrophy may give rise to enormous enlargement of the organ, in which case the heart is often spoken of as a “beefy heart” or a “cor bovinum.” This is especially apt to occur in aortic valvular disease and prolonged hypertension.

For the development of full hypertrophy, an adequate blood supply is necessary, and in this connection, as well as the anatomical and physiological

condition of the coronary arteries, the state of the general nutrition is of considerable importance.

Symptoms.—The symptoms of the morbid condition which is the cause of the hypertrophy, whether of the left or right side of the heart, may be present. With regard to the hypertrophy itself, there may be a complete absence of subjective symptoms. On account of increased tension in the cerebral circulation, there may be a sensation of fullness and throbbing in the head, headache, usually in the occipital region, flushings, noises in the ears, flashes of light before the eyes, and giddiness. Sometimes patients complain of discomfort or palpitation, and actual pain in the præcordium, especially when lying on the left side, aggravated by exertion. Actual pain, however, is not common, unless perhaps in the case of neurasthenics and of subjects of tobacco poisoning. The subsequent history varies greatly, according to the cause and degree of the hypertrophy, the state of the myocardium, and of the coronary and systemic arteries. There may be severe secondary dilatation and severe cardiac failure; and some degree of both is apt to supervene in all cases of long-continued hypertrophy.

✓ Hypertrophy of the left ventricle is characterised by a full strong pulse, of prolonged duration, and the blood-pressure may be above the normal. The pulse-rate, on the other hand, is apt to be rather lower than normal. There may be some bulging and widening of the intercostal spaces in the præcordial area to the left of the sternum, especially when the hypertrophy occurs during the growing period of life. The apex-beat is displaced downwards and outwards; it may be as low as the sixth, seventh, or even eighth intercostal space. Its area and force are increased, and the out-thrust is slower and longer than normal. *The increase in force, together with slowing of the out-thrust—the so-called “heaving” apex-beat—is the most characteristic feature of the condition.* The area of cardiac impairment is increased, both from above downwards and transversely; it may even extend downwards to the eighth interspace, and transversely to the anterior axillary line. On auscultation, the first sound in the mitral area is frequently long, low in pitch and muffled, and sometimes is reduplicated, the last being usually best heard rather to the inner side of the apex-beat; the short pause may be lengthened, and the long pause shortened, while the second sound in the aortic area is frequently accentuated and occasionally reduplicated.

When cardiac dilatation associated with heart failure supervenes, the pulse-rate may increase and the blood-pressure becomes lower, and physical signs of dilatation may be evident.

In hypertrophy of the right ventricle there may be, more especially in children, a certain amount of bulging in the region of the ensiform cartilage, while not infrequently there is pulsation in the epigastrium. When the condition is marked, there may be a heaving impulse in the epigastrium, and over the lower sternum and costal cartilages, and in such cases even in a more marked degree than in the case of the left ventricle. The apex-beat is displaced chiefly to the left and only slightly downwards, and may be normal, diffuse and indefinite, or altogether invisible. When the right ventricle is much enlarged, that chamber may displace the left ventricle backwards, so that the clinical apex-beat is formed entirely by the right, instead of the left, ventricle; in these cases systolic recession over the lower part of the præcordium is sometimes observed. Systolic recession in the third, fourth

and fifth intercostal spaces between the margin of the sternum and the parasternal line on the left side, or in the fourth and fifth intercostal spaces on the right side, may be present. The area of cardiac impairment is usually increased, especially to the right. The left border may also be displaced outwards, but rarely extends beyond the nipple line. The first sound in the tricuspid area is not infrequently louder than normal, and the second sound in the pulmonary area is usually accentuated and may be reduplicated. Later, indications of tricuspid incompetence may supervene.

When hypertrophy of the auricles occurs, it is accompanied by dilatation. In hypertrophy of the left auricle, the area of impairment may be higher than normal. When the right auricle is affected, there may be an extension outwards of the area of impairment in the third and fourth right intercostal spaces.

Diagnosis.—A diagnosis of hypertrophy of any chamber or chambers of the heart should not be made merely from the presence of pulsation or percussion impairment in an abnormal area, for these may be due to causes other than hypertrophy, as, for example, morbid conditions of the lungs or pleuræ. The most reliable sign of hypertrophy of the heart is a heaving impulse. It should be remembered that mere increase of force of the apex-beat is sometimes met with in nervous subjects, especially in the young whose chest-walls are thin; but in these cases there is no displacement of the apex-beat, the impulse is sharp and short, the area of impairment is not increased, and the sounds of the heart are not altered in the characteristic manner described. An incorrect diagnosis of hypertrophy of the left ventricle may be made in cases of retraction of the left lung. The apex-beat, however, is displaced upwards, is not heaving in character, and there are signs of a pulmonary lesion. Hypertrophy of the right ventricle can be diagnosed when the objective signs already mentioned are present. The diagnosis of hypertrophy of the left auricle is exceedingly difficult; hypertrophy of the right auricle is more easily detected.

Prognosis.—This depends upon, among other things, the cause, the degree of hypertrophy, the degree of dilatation present, the condition of the myocardium, and of the coronary and systemic arteries. With regard to the first, the prognosis depends very largely upon whether this is serious and irremediable, as when prolonged hypertension or chronic renal disease is present, in which case dilatation is apt to supervene; or whether it is merely transitory, as, for example, when the result of a period of excessive muscular strain, in which case it seems clearly established that hypertrophy may disappear when the cause no longer exists. Whatever the cause, long-continued hypertrophy is apt to be followed by dilatation, which adds to the gravity of the condition as a whole. With regard to the integrity of the myocardium, the importance of testing the cardiac response has already been fully considered.

With regard to the condition of the coronary arteries, it need only be pointed out that anginal attacks in all probability point to the existence of coronary disease, in which case the supply of blood to the hypertrophied heart will be insufficient, with a resultant tendency to fibrous or fatty degeneration of the myocardium.

Treatment.—The cause of the condition should be thoroughly investigated and treated. In order to provide a good supply of food to the heart-

muscle, we should see that the patient obtains plenty of fresh air and an adequate supply of nutritious and easily digestible food, and any existing anæmia present should receive attention. It is particularly important to avoid physical or mental stress or strain. If cardiac failure supervene, it should be treated as described elsewhere.

DILATATION OF THE HEART

In cardiac dilatation there is an increase in the capacity of one or more of the cavities of the heart.

Looking at the condition from the pathological standpoint, the muscular walls of the chambers may be of normal thickness, which is not common; more usually they are either thinner or thicker than normal. The last is by far the most common, i.e. in the great majority of cases there is some hypertrophy with the dilatation; this is called excentric hypertrophy, and has already been described. It should be remembered that when dilatation has existed for a long time, the walls become thin, although, perhaps, in the first instance thickened.

Looking at the subject from the clinical standpoint, however, dilatation means an increase in the capacity of one or more of the cavities of the heart as the result of impairment of the function of tonicity; this form of dilatation is associated with cardiac failure. From this point of view, dilatation with hypertrophy is only included when the dilatation is in excess of the hypertrophy. Hypertrophy is apt to be followed by dilatation, and the latter, therefore, may be secondary to the former.

In dilatation a larger quantity of blood exists in the affected chamber than normal, while the propulsive power is diminished; the chamber, therefore, cannot empty itself. As the dilatation progresses, the contraction of the chamber becomes less effective, and the amount of residual blood progressively increases.

Ætiology.—General cardiac dilatation may occur in any of the following conditions: rheumatic carditis; toxæmias, as in influenza, diphtheria, and alcoholism; severe or prolonged pyrexia from any cause; the various forms of anæmia; chronic valvular disease; and chronic myocardial disease. In the acute carditis of rheumatism, as well as in the toxæmia of influenza and diphtheria, dilatation may be acute. *It should be particularly noted that a very common clinical condition in which acute cardiac dilatation occurs is the supervention of a new cardiac rhythm, such as auricular fibrillation.* Dilatation may occur secondarily to hypertrophy whatever its cause. One of the most common causes of secondary dilatation is some form of mechanical obstruction, slowly produced, either in the blood-vessels or in the valves. Some of the causes of hypertrophy may produce acute dilatation by acting quickly, before there is time for hypertrophy to occur; this is especially the case when the muscular fibres are already impaired. Thus, whereas prolonged and continued excess of muscular effort tends to produce hypertrophy, a sudden physical strain is apt to produce acute dilatation, especially if the individual be not in training; further, in cases of completely established hypertrophy, dilatation may be produced with apparent suddenness by a comparatively trivial ailment, such as any febrile attack.

The causes of dilatation of the right side of the heart are the same as those of tricuspid incompetence (see p. 917). In addition, in cardiac failure whatever the cause, the pressure in the right chambers of the heart rises, and the chambers dilate. Dilatation of the right side of the heart may also occur in pleurisy with effusion. Dilatation of the auricles is especially apt to occur in auricular fibrillation.

Pathology.—Dilatation rarely affects one chamber alone, all of them being usually affected in some degree, although unequally so. The heart becomes larger, and when the condition is more or less general the organ approaches the globular form, particularly when the right side is affected. With the increase in the capacity of the ventricles, the dimensions of the auriculo-ventricular orifices also increase, and this results in what is known as *relative* incompetence. In dilatation of the auricles there is usually enlargement of the venous channels.

Symptoms.—The symptoms of the cause are usually to be noted. In addition, shortness of breath, fatigue, palpitation, and it may be giddiness or faintness, or even actual syncope, on exertion are the commonest symptoms. There may be præcordial discomfort or pain, and some degree of cyanosis of the face is sometimes present. Indications of severe, or even extreme, cardiac failure may supervene. These are chiefly pulmonary and those of systemic venous congestion; less frequently those of cerebral anæmia; and rarely angina.

The symptoms of cardiac failure may come on rapidly in the acute forms, or more gradually in the more chronic cases. In many of the cases associated with the onset of a new cardiac rhythm the dilatation may take place so rapidly that in the space of only a few hours there may be urgent dyspnœa, considerable enlargement of the heart, œdema of the lungs, and enlargement of the liver.

When dilatation is due to a sudden physical strain, faintness, passing into actual syncope, together with vomiting, and even fatal syncope, may occur before the signs of venous stasis have had time to develop.

The pulse in cardiac dilatation is usually more frequent, of smaller amplitude, and weaker, and the blood-pressure lower than normal. The apex-beat is displaced chiefly outwards. It is diffuse and often impossible to locate, but if it can be determined is found to be weaker than normal and may be tapping in character. In dilatation of the left ventricle a diffuse wavy impulse may be present even as far out as in the anterior axillary line. The area of cardiac impairment is increased transversely, and is more marked to the left when the left ventricle is chiefly involved. On auscultation, both cardiac sounds are found to be weaker; and, further, the first sound is short, sharp and clear, resembling the second sound in character. The long pause is often diminished, on account of acceleration of the rate of the heart, and sometimes the tic-tac rhythm is present. Occasionally gallop rhythm is to be noted. A mitral systolic bruit may be present on account of relative incompetency of this valve.

In dilatation of the right ventricle sometimes, particularly in children, there is a certain amount of bulging of the sternum in the region of the ensiform cartilage. The increase in the area of cardiac impairment is more marked to the right. A tricuspid systolic bruit may be present, due to relative incompetency of this valve. In dilatation of the left auricle, the

area of cardiac impairment may be higher than normal, and in dilatation of the right auricle it may extend outwards in the third and fourth right intercostal spaces.

The physical signs of dilatation enumerated above may be modified by those of the cause of the condition or of accompanying hypertrophy.

In the case of chronic valvular disease, any pre-existing murmur or murmurs may become weaker or even inaudible when dilatation occurs.

Diagnosis.—A diagnosis of cardiac dilatation can readily be made when the physical signs described are present. The diagnosis of dilatation from hypertrophy is easy on a comparison of the physical signs of the two conditions. When hypertrophy and dilatation coexist in the same individual, there is a blending of the signs of both. It is sometimes difficult to diagnose great dilatation, especially of the right ventricle, from pericardial effusion. The points relating to the differential diagnosis will be fully discussed under pericarditis. Cardiac dilatation must also be distinguished from those cases of mitral stenosis in which there is an absence of a presystolic murmur at the time of examination. It is, further, sometimes necessary to exclude a right-sided pleural effusion displacing the heart to the left, in which case signs of fluid in the right pleural sac will be found.

Prognosis.—The prognosis of cardiac dilatation depends, among other things, upon the cause, the degree of dilatation and whether this is out of proportion to the cause, the degree of any coexisting hypertrophy, the degree of cardiac failure, the rate and force of the pulse, the vigour of the apex-beat or of the impulse of the right ventricle, and the size of the heart. Taking cases of cardiac dilatation as a whole, the prognosis is unfavourable.

In acute dilatation from temporary causes, such as sudden physical strain or acute disease, if immediate danger can be tided over, there is a prospect of complete recovery, provided an adequate period of rest is available. The same applies to those cases due to the inception of a new cardiac rhythm, if the rhythm return to the normal, failing which if the ventricular rate can be controlled. In chronic dilatation from a permanent cause, *e.g.* chronic valvular disease, complete recovery is improbable; it may take place, however, in some instances under suitable treatment. The prognosis is very unfavourable when dilatation supervenes upon marked arterial disease or chronic myocardial disease, and this applies also to cases of Bright's disease.

Treatment.—The first thing that requires consideration is the recognition of the cause of the condition, whatever its nature, and suitable therapeutic measures should be employed in this connection. Added to this is the treatment of the affection itself, which is that of cardiac failure, and consists of an adequate period of rest, dieting, perhaps the administration of cardiac tonics or stimulants, and symptomatic treatment. Rest is imperative, and in acute cases must be absolute. Graduated exercises may be of service in a small group of cases, as, for example, in fatty infiltration. With regard to the administration of cardiac tonics, such as digitalis, the reader is referred to the appropriate section for their indications, dosage, and method of administration. When dilatation is due to bacterial poisoning, digitalis appears to be of little or no value. The various therapeutical measures described on pp. 832–847 should be carefully considered in detail.

FREDERICK W. PRICE.

DISEASES OF THE PERICARDIUM

PERICARDITIS

The varieties of pericarditis which may be met with are the fibrinous or dry sero-fibrinous, purulent, hæmorrhagic, and chronic adhesive, i.e. adherent pericardium. Some writers describe the chronic form of pericarditis; this, however, is practically synonymous with chronic adhesive pericarditis.

ACUTE PERICARDITIS

Ætiology.—It is questionable if pericarditis is ever primary or idiopathic. The affection occurs most commonly in childhood and adolescence, and is more frequent in males. Acute and sub-acute rheumatism, in one of its forms (see p. 886) is by far the most common cause. It is not infrequent in acute infective diseases, especially pneumonia and scarlet fever; in the former, infection may take place either by means of the bloodstream or by extension. Among other causes are tuberculosis (see p. 944); septic conditions; as a terminal event in chronic diseases, such as Bright's disease, particularly the chronic forms, and diabetes; disordered states of the blood, for example, leukæmia; acute coronary infarction; affections of the neighbouring parts, e.g. the pleuræ, lungs, mediastinum, ribs, vertebræ and peritoneum; injuries to the chest wall; and in conjunction with myocarditis.

When pericarditis is due to Bright's disease, there is a tendency to the purulent, hæmorrhagic, or chronic adhesive variety of the disease. The pericarditis which occurs in connection with malignant disease is usually of a chronic type, and is generally accompanied by the effusion of fluid, which is usually hæmorrhagic, but may be purulent or serous. Purulent pericarditis is usually due to pyæmia, septicæmia, as in the exanthematous fevers, or suppuration in the neighbourhood of the pericardium, as, for example, empyema, or the rupture of a pulmonary vomica. It may also occur in Bright's disease, and in tuberculous deposits in the pericardium. Among the micro-organisms which may be found are staphylococci, streptococci, pneumococci and gonococci. Hæmorrhagic pericarditis is more frequently met with in the aged, in Bright's disease, in acute infective conditions, such as small-pox, tuberculosis, scurvy and purpura, malignant disease, either by direct extension or secondary, wounds of the heart, and in leakage from an aneurysm.

Pathology.—Pericarditis may be general or local; if the latter, the base of the heart, close to the region of the great vessels, is, as a rule, principally affected.

In the fibrinous form, the free surface of the pericardium becomes more vascular and loses its smooth shiny appearance, owing to the transudation of lymph which coagulates and forms a fibrinous exudate, which in the course of time may involve the entire surface, visceral and parietal. Usually the exudate may easily be separated from the underlying surface, often leaving a honeycomb or reticulate appearance. In the fibrinous form there is little or no effusion of serum into the pericardial sac. In the sero-fibrinous form, on the other hand, complete resolution of the fibrin, and, in the latter case,

absorption of the effusion, may take place, so that no trace of the inflammation is left. When, however, resolution of the fibrin and absorption of the fluid occur slowly, which is the rule in the sero-fibrinous form, organisation takes place. This may give rise to white patches of thickening ("milk spots") upon the pericardium, or may result in its two layers becoming adherent by permanent fibrous adhesions; in the latter event, chronic adhesive pericarditis or adherent pericardium is produced. In purulent pericarditis the pus rarely perforates the pericardium, and has been known to become absorbed, leaving behind a pultaceous mass.

It may be noted that some degree of myocarditis is always present with pericarditis.

Symptoms.—In the first place, the reader is referred to the remarks on p. 886.

The severity of the symptoms of the disease itself exhibits great variation, and there may be a complete absence of subjective symptoms throughout the whole course; on auscultation, however, pericardial friction is usually found.

If pyrexia be already present, there is usually a further slight rise of temperature. Occasionally the onset of the disease is marked by a rigor. The patient is usually pale, and sometimes cyanotic. Præcordial uneasiness, or even pain, may be present, but is far less common than is generally supposed; the pain may be located in the epigastrium, the left scapular or interscapular region, instead of in the præcordium, and varies greatly in severity and character. It may be constant and dull, or recurring, sharp and stabbing; anginal attacks are rarely to be noted. Sometimes palpitation and breathlessness are complained of, and there may be faintness. The respiratory rate may be increased, and there may be rapid, shallow respiratory distress, or even cardiac asthma or Cheyne-Stokes respiration. Not infrequently a dry cough is present. Dysphagia is of uncommon occurrence, being more marked when the patient is in the recumbent posture. When the recurrent laryngeal nerve is implicated, the voice becomes affected, while if the phrenic nerve be involved the patient may suffer from hiccough. There may be headache, restlessness, insomnia, convulsions, mild nocturnal delirium, or, less frequently, noisy delirium, stupor, and even coma.

Hepatic enlargement is of comparatively common occurrence. A certain amount of oedema may become evident; it is usually general and is more marked in the dependent parts. The usual indications of severe cardiac failure, usually those of pulmonary and systemic venous congestion, may supervene.

The pulse is increased in rate and smaller in volume; and after a period, the blood-pressure becomes lower. At first the apex-beat may be excited and its force even considerably increased; later it becomes diminished in force, sometimes tapping in character and displaced outwards. Friction-fremitus can sometimes be noted in fibrinous pericarditis. Its area of maximum intensity does not absolutely correspond with that of a thrill due to valvular disease. As a rule, friction-fremitus accompanies ventricular systole and diastole, having a to-and-fro character, but sometimes it is only systolic; in any case it is not exactly synchronous with either systole or diastole. It gives the impression to the hand of being superficial. After a period, the area of deep cardiac impairment may become enlarged to the left, upwards, and to the right. Auscultation reveals pericardial friction.

It may accompany every phase of the cardiac cycle. As a rule, it accompanies ventricular systole and diastole, is of a to-and-fro character, with usually a short pause between the two portions. Sometimes it is only ventriculo-systolic, while at other times, when the inflammation involves the auricle, it accompanies auricular systole, ventricular systole, and ventricular diastole, giving rise to a triple rhythm. In any case, the different portions of the friction sounds do not, absolutely coincide either in rhythm or duration with any period of the cardiac cycle, being rather later than any of them and usually heard during portions of more than one period. The adventitious sound is usually first audible over the base of the heart, but later on may become audible over the whole præcordium. The area of maximum intensity does not absolutely correspond with that of any of the valvular areas. A characteristic feature is that, as a rule, the sound is either not at all or only slightly conducted, and there is no definite selective direction of propagation. It is of a rubbing quality, either fine and creaking or coarse and grating, and is superficial, giving the impression of being produced immediately beneath the stethoscope, while moderate additional pressure with the stethoscope usually causes an increase in its intensity. The friction may not be so well heard when the patient is lying down as when he is sitting up, and its loudness may be also influenced by respiration, being, as a rule, louder during inspiration—in contra-distinction to pleural friction. The heart sounds are usually audible. There may be doubling of the first sound, giving rise to a triple rhythm, while a mitral systolic murmur is not infrequently present, due either to coexisting endocarditis or to cardiac dilatation.

As the exudate is absorbed the friction gradually disappears, but it usually remains, unless the quantity of fluid is great, and even then it may persist—this being in marked contrast with friction occurring as the result of pleuritis. If the friction persist, it occupies a higher level than before. When pericarditis is secondary to pleurisy or pneumonia, there is often pleuro-pericardial friction along the left border of the heart, where the pleura lies in front of the pericardium. This also occurs in cases of pericarditis in which the outer surface of the pericardium and the opposing pleural surface become involved.

When effusion has occurred, usually there is no increase of temperature, and, indeed, if the pyrexia has been marked, there is a tendency for it to become lower. The pallor and any existing cyanosis become more pronounced, and there is usually an anxious expression. Interference with the respiratory functions is more evident, and may be greatly aggravated unless the effusion of fluid is gradual. Dysphagia becomes more marked.

The early physical signs of sero-fibrinous pericarditis are those of the fibrinous variety. The pulse becomes still more frequent, smaller in volume, and the blood-pressure lower. The pulsus paradoxus may be present. Not infrequently there is prominence of the præcordium, and, if so, the intercostal spaces may be widened or even bulge, as well as the ribs, and there may also be prominence of the epigastrium. The apex-beat is often displaced upwards, usually in the fourth, but sometimes in the third, interspace, and it may be to the left of the nipple line. Sometimes it is more mobile than normal. It is more distinct in the recumbent posture than when the patient sits upright, on account of the tendency of the fluid to gravitate backwards when lying down, and forwards when sitting

up. As the amount of effusion increases, the apex-beat becomes less and less distinctly felt, until it may be quite imperceptible. There may be diminished movement of the left chest. Friction-fremitus may be present, but not in the same degree as in the fibrinous variety. The most characteristic physical signs are those obtained by percussion. The areas of superficial and deep cardiac impairment are increased, in some cases considerably; this increase takes place in all directions, and is progressive. Some observers believe that in the early stage of pericardial effusion, impairment of the percussion note may be found in the fifth right intercostal space, between the costal cartilages, where the right margin of the heart forms an angle with the liver (Rotch's sign). When the effusion is considerable, the form of increased area of cardiac impairment is characteristic. In the standing position, the base is narrowed, and the outline of the shadow, as a rule, closely resembles that of a pear hanging downwards by its stalk, or of a water-bottle. When the patient is in the recumbent position, the base is broadened, and the form of the shadow is globular. The area of relative impairment often extends well to the left of the apex-beat; it may be almost to the left mid-axillary line. The right border may be found considerably to the right of the sternum. The extension upwards may be as high as the left clavicle, the upper lobe of the left lung being compressed. The lower limit may reach the lower margin of the sixth rib. In the recumbent posture the area is smaller than when the patient sits upright, on account of the tendency of the fluid to gravitate backwards in the one case and forwards in the other. The degree of impairment is absolute. On auscultation, the heart-sounds are found to become progressively indistinct and muffled, and may be lost, though sometimes, even when the quantity of fluid is large, they may persist, especially at the base; this also holds good with regard to friction.

The pressure of the effusion upon the lungs may result in the production of dullness and diminished breath sounds at the extreme left base close to the spinal column; as well as skodaic resonance, tubular breathing, and ægophony, not only over a patch in the neighbourhood of the angle of the left scapula, but also over the borders of the lungs anteriorly; the upper limit of the area of impairment posteriorly may shift on change of position. Pleural effusion on both sides is not uncommon. The liver and spleen also may be pushed downwards.

On X-Ray examination, the outline of the heart itself is vague or absent. When the amount of effusion is moderate, there is general enlargement of the shadow. When considerable, its form is characteristic and alters with the position of the patient. On screening, there is a diminution or absence of the cardiac pulsation. Any existing displacement of the liver or spleen may be noted.

As the fluid becomes absorbed, the area of cardiac impairment diminishes, the heart sounds gradually return to the normal, and, as the two surfaces of the pericardium come once more into contact, friction may reappear.

The symptoms of purulent pericarditis are those of the sero-fibrinous variety, except that rigors, a high and fluctuating temperature, profuse perspirations, great wasting, pallor, rapid prostration, marked rapidity of the pulse-rate, a subnormal blood-pressure, a relatively smaller area of cardiac impairment, and an absence of pericardial friction are more likely to occur. It should be noted, however, that the temperature may be almost

normal, and cases have been reported in which it was even subnormal; and there may also be little alteration in the frequency of the pulse or respiration. Sweatings may occur without the existence of rigors. An examination of the blood usually reveals a leucocytosis. When pus is present from the first, the subjective symptoms may be obscured by those of the associated condition, and only the physical signs of pericarditis with effusion may be noted; though even then there may be no increased area of impairment and an absence of friction.

Diagnosis.—It is exceedingly important to be on the look-out for an insidious or masked attack of pericarditis.

The diagnosis of the fibrinous variety of pericarditis is not, as a rule, difficult, and rests upon physical signs. Of these the most characteristic sign is the presence of friction sounds of the type already described. This is pathognomonic of fibrinous pericarditis, or of tuberculous, cancerous, or gummatous deposits, and should be differentiated from an endocardial murmur (especially if the friction sound be single), and from pleuro-pericardial friction. With regard to the first, in exocardial sounds whether due to pericardial friction or to pleuro-pericardial friction, the different portions of the friction sounds do not absolutely coincide either in rhythm or duration with any period of the cardiac cycle, being rather later than any of them and usually heard during portions of more than one period; the area of maximum intensity does not absolutely correspond with that of any of the valvular areas; the friction sounds are, as a rule, conducted either not at all or only to a slight extent, and there is no definite selective direction of propagation; they are of a rubbing quality; they give the impression of being produced immediately beneath the stethoscope, while additional pressure with the stethoscope usually causes an increase in their intensity; and, further, their position, intensity and character may alter in a few hours. With regard to the second, the friction is either much reduced or ceases when the patient stops breathing, while it is increased by respiration. Further, pleuritic friction usually disappears with the effusion of fluid, whereas in pericarditis with effusion, friction is not abolished unless the quantity of fluid is great, and even then it may persist.

Sero-fibrinous pericarditis can be diagnosed from the physical signs described, and the results of X-Ray examination

In the diagnosis of sero-fibrinous pericarditis, we should be careful to exclude dilatation of the heart, hydro-pericardium, left localised pleural effusion, pulmonary consolidation, thoracic aneurysm, new-growth, enlarged glands and abscess of the mediastinum. In each case the causation, mode of onset, and physical signs should be considered.

It is sometimes difficult to diagnose pericardial effusion from great dilatation of the heart, especially of the right ventricle. In pericardial effusion there is often bulging of the præcordium, with obliteration of the intercostal spaces; the apex-beat is internal to the left margin of percussion impairment, and may be displaced upwards to the fourth or even third interspace; the area of cardiac impairment may extend to the second left costal cartilage, the extension often coming on rapidly, and in form is pear-shaped, instead of increased transversely; the angle formed by the heart and liver impairment is obtuse, whereas in the case of an enlarged right heart it is acute or is at most a right angle; the percussion note is absolutely dull

and the sense of resistance greatly increased; and there may be evidence of displacement of the liver and spleen. On auscultation, the heart sounds are muffled, whereas in cardiac dilatation the characteristic physical signs already described are present.

Hydro-pericardium may be detected by noting the cause, the absence of friction during any period of the illness, and the presence of general anasarca, ascites, or pleural effusion.

A positive diagnosis of purulent pericarditis may be made by an exploratory puncture.

Prognosis.—In most cases the immediate prognosis of pericarditis is not unfavourable. The prognosis is more unfavourable at the extremes of life, and with a history of alcoholism. When the affection is due to rheumatism, the immediate prognosis is favourable in the great majority of cases; a fatal termination, however, sometimes occurs at the extremes of life. When due to Bright's disease, pneumonia, tuberculosis, acute infective conditions, and new-growth, the prognosis is unfavourable. A severe degree of dyspnoea, or of cyanosis, or pronounced mental symptoms are of unfavourable omen.

If the effusion be serous and moderate in degree, recovery is the rule, although adhesions result; if, on the other hand, the amount of fluid be large, the termination may be fatal, and this usually occurs during the second or third week. When the effusion is purulent, the prognosis is grave, especially if the pus be putrid, and a fatal termination may occur within a few days. The outlook is likewise grave when the effusion is hæmorrhagic in character. Death may be due to asphyxia, sudden syncope, especially on exertion while in bed, and more rarely asthenia.

With regard to the ultimate prognosis of pericarditis, time is necessary to determine whether adhesions have resulted, and, if so, their site and degree, and whether the myocardium has been permanently damaged and to what extent.

Treatment.—The general treatment of acute pericarditis is the same as that of acute endocarditis (see pp. 890, 891).

In cases of moderate effusion, the former treatment should be continued. If, however, the effusion become considerable, counter-irritation, the administration of iodide of potassium, purgatives, and diuretics, and limitation in the amount of fluid taken, are indicated. If the amount of effusion does not diminish, or if there is marked dyspnoea, cyanosis and a small rapid pulse, paracentesis pericardii should be performed. The site chosen for this procedure varies. It may be performed in the fifth left intercostal space just inside the mammary line; or quite near the margin of the sternum in the same space; or in the angle between the onsiform cartilage and the left costal margin of the sternum, near the lower end of the body of the sternum, and passing upwards and inwards behind it into the pericardial sac. Formerly a trochar and cannula, or a fine aspirating needle, was employed, but the use of an aspirator is now found to be preferable. Removal of fluid is rarely, if ever, necessary in cases of rheumatic origin; indeed, cases in which the fluid does not subside in due time are probably tuberculous.

The stage of convalescence requires careful management, on the same lines as those of acute endocarditis.

The treatment of purulent or hæmorrhagic pericarditis consists in free incision and drainage of the pericardial sac, unless the state of the patient is too grave to allow of it—in which case paracentesis may be performed, and, if improvement occur, incision and drainage may be subsequently permissible—or unless the condition is associated with a hopeless primary cause.

CHRONIC ADHESIVE PERICARDITIS OR ADHERENT PERICARDIUM

In this form of pericarditis the two layers of the pericardium are bound together by permanent fibrous adhesions.

Ætiology.—The condition usually results from a previous attack of acute pericarditis, especially if accompanied by effusion, or it may follow a primary chronic inflammation; the latter may be due to an extension of inflammatory processes from the neighbouring parts.

Pathology.—The degree of chronic adhesive pericarditis varies. It may amount to only thickening or scarring of the pericardial surface; or a few fine bands, most commonly situated at the base of the heart close to the great vessels, crossing the pericardial sac; or, in more severe cases, it may result in the formation of a layer of connective tissue, occasionally of considerable thickness, which more or less completely unites the two layers of the pericardium. The formation of partial synechiæ, however, is a much more common result than obliteration of the sac. There may be chronic indurative mediastinitis, resulting in chronic indurative mediastino-pericarditis. Sometimes extra-pericardial adhesions exist. In this way adhesions may form between the pericardium and the mediastinal structures, the chest wall, the pleuræ, or the diaphragm. In rare instances, extra-pericardial adhesions are found in the absence of adhesions between the two layers of the pericardium. In advanced cases, pericardial adhesions may become more or less completely calcified, owing to the deposition of lime salts. There may be co-existing chronic myocarditis, chronic valvular disease, or both.

In a large proportion of cases, cardiac hypertrophy, usually accompanied by dilatation, exists. The enlargement is in all directions, but the ventricles are especially affected. The degree of enlargement varies with the position and nature of the adhesions, and the existence or otherwise of chronic valvular disease or chronic myocarditis: it may be small, or altogether absent, even when the sac is completely obliterated, provided the sac is not thickened and there is an absence of extra-pericardial adhesions, and valvular and myocardial disease; whereas it may be markedly so if the reverse is the case.

The openings of the large vessels entering and leaving the heart may be constricted by the adhesions, and thus may interfere with the influx and egress of blood. The *venæ cavæ* are most affected. Constriction of the hepatic veins may lead to chronic venous congestion and ultimately some degree of cirrhosis of the liver—*pericardiac pseudo-cirrhosis of the liver*, or Pick's disease.

Symptoms.—The condition may be latent throughout its whole course. If symptoms are present, they may exhibit considerable variation. Shortness of breath, pain and palpitation are the most frequent. There may be dragging pain in the præcordium, sometimes extending considerably beyond it, while anginal attacks have been known to occur. There may be indications of severe cardiac failure, principally pulmonary, and those of systemic venous

congestion : if the left ventricle is most affected by the adhesions, particularly the former ; and if the right ventricle, especially the latter.

The pulse may exhibit the characteristics of *pulsus paradoxus*. The præcordium may be prominent ; less commonly there is flattening. The apex-beat is usually displaced, and its position does not vary with change of posture—a fact which also applies to the area of cardiac impairment. The area of pulsation is usually greatly increased, and may even extend from the second to the sixth intercostal space, and almost from the right parasternal line beyond the left mammillary line ; it may be wave-like and undulatory in character. If adhesions between the pericardium and chest-wall exist, indrawing of the apex-beat may occur, also with systolic recession of the intercostal spaces on either side of the sternum, of the lower end of the sternum and adjacent costal cartilages, and in the epigastrium ; while systolic retraction of the lateral and posterior walls of the left side of the chest, upon the latter of which Broadbent has laid great stress as indicating adhesion between the pericardium and diaphragm, is occasionally to be noted. Diastolic shock, or diastolic rebound, *i.e.* the shock felt by the hand during diastole, is rarely present at the apex-beat, or over a larger area of the præcordium, or even over the left lateral or posterior aspect of the chest. The position of the apex-beat and the area of cardiac impairment may be unaltered on deep respiration. Diminished expansion of the left side of the chest, and incomplete descent of the left half of the diaphragm during inspiration, as shown by diminished movement of the upper part of the abdominal wall on the left side, may be noted. Diastolic collapse of the veins of the neck—Friedreich's sign—is occasionally met with.

The area of cardiac impairment is usually much increased, both to the right and to the left. Bruits indicative of relative incompetence, both of the mitral and tricuspid areas, may be present. Some authorities are of opinion that a rumbling mitral presystolic bruit is sometimes heard in adherent pericardium in children ; this bruit, however, is not rough or vibratory in character, nor does it terminate abruptly in the first sound, as in the case of mitral stenosis. There may be physical signs of coexisting heart disease.

In *pericardiac pseudo-cirrhosis of the liver*, hepatic enlargement and ascites are disproportionate to, or occur in the absence of, œdema of the legs.

On X-Ray examination, the cardiac shadow may be enlarged in all directions, the ventricles being particularly affected. There may be diminution or complete absence of alteration of the position of the apex-beat and of the heart with change of posture and on deep respiration, and of movement of one or both sides of the diaphragm. Vaquez emphasises the importance of elevation of the shadow with deep inspiration, which is the reverse of that which occurs normally, as being indicative of adhesions between the pericardium and the anterior chest wall. Systolic retraction of the posterior wall of the left chest may be observed in adhesions between the pericardium and diaphragm. Occasionally adhesions may be detected, the borders of the heart and the adhesions themselves appearing as shadows of vague and irregular outline. In advanced cases, calcification of the thickened pericardium may be noted.

Diagnosis.—The diagnosis may be a matter of considerable difficulty. A positive diagnosis should not be made from the presence of one physical sign only, except when diastolic shock or rebound exists, and perhaps also

in those cases in which systolic recession of the sternum itself is present. Diastolic collapse of the veins of the neck when associated with recession of the intercostal spaces on either side of the sternum is a most valuable sign. It should be noted that the pulsus paradoxus, indrawing of the apex-beat, and systolic recession in the intercostal spaces on either side of the sternum, or in the epigastrium, or even of the lateral or posterior walls of the left side of the chest, do not necessarily indicate the existence of chronic adhesive pericarditis; and, further, that an absence of alteration of the position of the apex-beat and of the area of cardiac impairment with change of posture or deep respiration may also be present in pleural adhesions. When, however, several or all of the physical signs of the affection are present a positive diagnosis is warranted, especially if there be indications of right-sided cardiac enlargement or failure in the absence of mitral or pulmonary disease. X-Ray examination is sometimes of notable assistance, especially in the case of extra-pericardial adhesions. A history of acute pericarditis or of a rheumatic infection is of additional assistance, although, on the other hand, it should be remembered that the affection may be chronic from the beginning.

When signs of cirrhosis of the liver and ascites appear in a young subject, pericardiac pseudo-cirrhosis of the liver should be suspected.

Prognosis.—This depends upon the situation, extent and nature of the adhesions, the size of the heart, the existence or otherwise of valvular disease, the degree of integrity of the myocardium, and the degree of cardiac failure which may be present. The prognosis may be good, and, indeed, the patient's longevity may not be affected; or, on the other hand, it may be grave, especially in early life.

Treatment.—The treatment of the condition consists in counter-irritation externally, and the internal administration of iodide of potassium during the later stage of the attack of acute pericarditis as a prophylactic. When adhesions have formed, detailed instructions should be given to the patient to curtail his physical and mental activities so as not in any way to exceed the limited strength of the heart. When cardiac failure supervenes, it should be treated on the lines previously laid down.

It may be necessary to consider the advisability of performing the operation of "cardiolysis" in some cases of severe adhesions between the pericardium and the chest-wall. This operation was introduced by Brauer in 1902, and is indicated when there is also evidence of cardiac failure and ordinary treatment has failed; but the operation should not be unduly delayed. It is usually not necessary during childhood or adolescence, because of the flexibility of the chest-wall. The operation consists in the resection of the fourth, fifth and sixth ribs on the left side, and, where possible, freeing the adhesions.

CHRONIC PERICARDITIS

It has been already noted that some writers describe a chronic form of pericarditis. This, however, is practically synonymous with chronic adhesive pericarditis or adherent pericardium, although it sometimes happens that in acute pericarditis with effusion, especially when due to tuberculosis, the effusion may persist for an indefinite period and the condition become a chronic pericarditis, resulting in considerable thickening of both layers of

the pericardium. Further, but less frequently, pericarditis may be chronic from the first, especially in the aged, in alcoholism, and in nephritis.

When the result of acute pericarditis, the symptoms are those of that stage of the disease at which it became chronic. When chronic from the first, the affection is not infrequently latent throughout its whole course; there may, however, be dyspnoea, a sense of oppression, and rarely pain, in the præcordium, an increase in the area of cardiac impairment, feeble cardiac sounds, and sometimes pericardial friction.

TUBERCULOSIS OF THE PERICARDIUM

Tuberculosis of the pericardium may be primary, or part of an acute general tuberculosis, or secondary to that of the lungs, the pleuræ, the mediastinal or bronchial glands. It may give rise to—(1) Tuberculous pericarditis, in which the effusion may be clear, purulent or bloodstained, and in which tuberculous nodules with giant cells are sometimes found in the fibrous tissue consequent upon organisation; (2) miliary tubercles, which may be seen along the course of the small blood vessels in the epicardium, especially in the sulci; and (3) larger tubercular masses in the epicardium, situated particularly at the base of the heart, and presenting a yellow caseating centre. The two latter conditions are much less common than the first. There is a greater tendency to the chronic type of pericarditis in the case of tuberculosis than when due to other causes, the condition persisting for several weeks or even months, and not infrequently giving rise to a layer of connective tissue of considerable thickness, more or less completely uniting the two layers of the pericardium; there may or may not be fluid, which is frequently bloodstained, and is occasionally purulent.

Symptoms.—The affection (1) may be entirely latent throughout its whole course; (2) may present the symptoms of acute pericarditis, with, in addition, loss of weight and strength, a fluctuating temperature, a tendency to chronicity, and ending in effusion of fluid or the formation of adhesions; (3) may be a chronic adhesive pericarditis, with consequent hypertrophy and dilatation, and ultimately indications of cardiac failure; or (4) may present the symptoms of acute tuberculosis.

Diagnosis.—This can be made from an absence of any history of rheumatism or other cause of pericarditis, and, further, there may be evidence of tuberculosis elsewhere.

Prognosis.—This is very grave.

Treatment.—The treatment is that of pericarditis due to other causes, together with that indicated in ordinary tuberculosis, such as an abundance of fresh air, a generous diet, and the administration of cod-liver oil.

HYDRO-PERICARDIUM

Definition.—A certain amount of fluid is usually found in the pericardium after death; in hydro-pericardium, or dropsy of the pericardial sac, this is in excess. The fluid is clear, pale amber in colour, and has a specific gravity of about 1015.

Ætiology.—The condition is always secondary. It may occur along with ascites, hydro-thorax, and general anasarca, in valvular or myocardial disease, or in nephritis. Or it may occur alone, as the result of pressure upon the veins of the pericardium or of the heart by aneurysm, enlarged glands, or new-growth of the heart, pericardium, or mediastinum; from constriction of the veins by adhesions; and in various cachectic conditions, scarlet fever, and some purpuric conditions.

Symptoms.—The symptoms of the primary affection are usually to be noted. The condition in itself does not give rise to pyrexia or præcordial pain. There may, however, be a sense of oppression in the chest, dyspnoea, cyanosis, attacks of faintness or even unconsciousness, œdema, hepatic enlargement, and scanty urine. In some cases there is drowsiness or mild muttering delirium. The pulse is soft, and of subnormal pressure. On examination of the heart, the physical signs are found to be those of pericarditis with effusion, except that there is an absence of friction on auscultation.

Diagnosis.—A diagnosis may be arrived at by a consideration of the cause, signs of fluid in the pericardial sac, and an absence of friction.

Prognosis.—The prognosis is that of the primary affection.

Treatment.—This is based upon the causal condition, and, in addition, a lessened intake of fluid, together with the use of purgatives and diuretics, are indicated. If urgent symptoms appear to demand it, paracentesis may be performed; this, however, is rarely necessary.

PNEUMO-PERICARDIUM

Definition.—By pneumo-pericardium is meant the presence of air in the pericardial sac. It is a very rare condition. Pericarditis is always present, with serous (pneumo-hydropericardium), purulent (pneumo-pyopericardium), or hæmorrhagic (hæmopericardium) effusion.

Ætiology.—The affection may be due to wounds through the chest-wall, or the result of communication with an air-containing cavity, such as occurs in abscess or gangrene of the lung, malignant disease of the œsophagus, gastric ulcer, and hepatic abscess. It is further believed by some that gas may be spontaneously generated within the pericardial sac *intra vitam*.

Symptoms.—Breathlessness, præcordial discomfort or even pain, faintness and cyanosis are the most constant symptoms. There may be a certain amount of bulging of the præcordium, and the apex-beat is diminished in force or even absent. On percussion, a tympanitic note is to be observed, the area of which changes with an alteration of posture. In the recumbent position it may be heard over most of the præcordium, while if the patient be sitting upright the lower part of the præcordium becomes impaired and the upper part hyper-resonant. On auscultation, metallic and splashing sounds, resembling those produced by a water-wheel or a churn, synchronous with the movements of the heart, are audible; these sometimes become more pronounced on shaking the patient, and occasionally may be heard at a considerable distance. Pericardial friction is sometimes also to be noted.

Diagnosis.—The diagnosis is not difficult when the physical signs enumerated are present. Care, however, should be taken to exclude a large pulmonary vomica in the neighbourhood of the heart, a left-sided pneumothorax, and dilatation of the stomach.

Prognosis.—The majority of cases die within the course of a few days. Traumatic cases, however, have been known to recover; the wound may heal and the air be absorbed.

Treatment.—In traumatic cases, paracentesis of the pericardial sac, with free incision and drainage if the fluid be purulent, is advisable. In other cases, treatment is usually palliative.

HÆMO-PERICARDIUM

Definition.—By this is meant the presence of blood in the pericardial sac, occurring apart from pericarditis.

Ætiology.—It may be due to punctured wounds, perforation of the œsophagus by a dental plate, rupture of the aorta, of one of the coronary arteries, or of the heart, or as the result of purpura or scurvy.

Symptoms.—Death may take place suddenly, or there may be sudden collapse, marked pallor, perspiration, or syncope, with a rapidly fatal termination. On examination, the pulse will be found to be feeble, and of low tension, with, perhaps, increased area of cardiac impairment.

Prognosis.—Except in some traumatic cases, where surgical interference is possible, the outlook is always hopeless.

Treatment.—This is limited to immediate surgical operation in certain cases.

OTHER DISEASES OF THE HEART AND PERICARDIUM

SYPHILITIC AFFECTIONS OF THE AORTA, THE HEART AND THE PERICARDIUM

THIS subject is one of great importance, and also of great difficulty, more especially with regard to the relative frequency and the diagnosis of the condition, for these are intimately bound up with ætiological and pathological considerations. I shall confine my remarks to the acquired form of the disease.

Pathology and Relative Frequency.—Acquired syphilis may attack the aorta, the cardiac valves, the myocardium, the pericardium and, in the opinion of most writers, very rarely the coronary arteries themselves.

The pathology of syphilis of the aorta (syphilitic mesoarteritis) and its results are described on pages 937, 947, 949, 837, 840 and 860.

The following considerations are among those noted: The ascending part of the aorta is the most commonly affected. Syphilis invades the aorta from without. The disease-process is the result of inflammation of the vasa vasorum and their terminations in the coats of the aorta. The adventitia and, later, the media of the areas of the aorta supplied by the inflamed vasa vasorum are secondarily affected, and the inflammation is mainly confined to

these coats. The inflammation in the media is followed by absorption and, it may be, necrosis of the elastic tissue and muscle-fibres, and at a later date by new formations of fibrous tissue. The intima over the areas of inflammation is usually thickened. This is merely secondary, and is protective or compensatory. In its earlier stages, it is to be distinguished from atheroma by the naked eye. It is to be added, however, that in the later stages, atheroma usually occurs in the thickened intima over the areas of inflammation; also that syphilitic mesaortitis and primary atheroma may co-exist, especially in later life.

The weakening of the middle coat of the aorta by syphilitic aortitis leads to dilatation of its lumen. This may be general (diffuse aneurysm), or localised (circumscribed or saccular aneurysm); the latter is usually accompanied by some degree of the former.

Syphilitic aortitis may give rise to narrowing or complete occlusion of the orifice of one or both of the coronary arteries and, in the opinion of most writers, syphilis may rarely affect the coronary arteries themselves (see p. 922). The disease-process in the aorta may involve the aortic valve (see p. 911), and occasionally it extends to the base of the aortic cusps of the mitral valve. For syphilis of the myocardium, see p. 924. The auriculo-ventricular junctional tissues may be involved, and such may give rise to auriculo-ventricular block. Syphilis of the pericardium is of rare occurrence. The disease most commonly attacks in the form of an infiltration, with consequent formation of fibrous tissue, resulting in adhesions between the two layers of the pericardium, while in some cases there is effusion of fluid into the pericardial sac. Gummata are less common.

Professor H. M. Turnbull found that in 288 necropsies at The London Hospital, in which lesions of acquired syphilis were present, the most common syphilitic lesion was mesaortitis. Syphilis is the cause of a large proportion of all cases of aortic incompetence, and also an important ætiological factor of angina pectoris, especially under the age of 40. But, in considering the relative frequency of syphilis in affections of the heart and aorta, there is now a danger of going to the other extreme. Thus, assertions that syphilis is responsible for a quarter to a third of the total number of cases of organic disease of the heart, for about three-quarters of all cases of aortic incompetence, and almost invariably for cases of aortic incompetence in which there is an absence of a definite history of acute rheumatism, should be accepted with the greatest reserve. Statistics appear to suggest that syphilis accounts for less than ten per cent. of all cases of organic heart disease in this country, though its incidence is higher in some non-European populations.

Symptoms.—The symptoms of syphilitic aortitis depend largely upon the extent of the lesion, that is, whether there is general dilatation of the aorta, aortic incompetence, involvement of the coronary arteries, fibrosis of the myocardium, or saccular aneurysm.

In the early stages, the patient may not complain of any symptoms, and for this reason X-Ray examination of the aorta is justifiable in patients with a history of syphilis or who present other syphilitic lesions.

In the early stages, before involvement of the coronary arteries or aortic incompetence, the most frequent symptoms are pain, severe paroxysms of dyspœa, and dyspnœa on exertion, especially the first. It is exceedingly important to recognise the characteristic features of the pain. It is usually

situated behind the upper part of the sternum, and is often localised there, but it may radiate to the arms and neck. It may vary from slight discomfort, or a sensation of oppression, to intense pain. It may be more or less constant, or intermittent. Occasionally there are paroxysms of pain, accompanied by a feeling of suffocation. The pain may come on spontaneously—that is, apart from physical exertion, especially when lying down—or it may occur only on exertion; it is usually aggravated by exertion; it may fail to disappear completely on cessation of exertion. There may be hyperæsthesia over the painful area. Not infrequently severe paroxysms of dyspnoea, and tachycardia may often be noted. The pain may disappear after a few months or weeks, either spontaneously or as the result of treatment. It may be followed by angina pectoris. Some observers are of opinion that sometimes, during the early stage, faint rubbing sounds along the right border of the sternum may be noted, especially when the patient leans forward; personally I have never been able to detect this.

Later, there may be manifestations of general dilatation of the aorta; of aortic incompetence; of coronary disease; of fibrosis of the myocardium; or of saccular aneurysm. In the first, there may be pulsation in the supra-sternal notch; rarely impairment of percussion over the manubrium sterni and on either side of it; not infrequently a systolic murmur over the aortic area; and the second sound in the aortic area is often accentuated, and may exhibit a tambour-like or bell-like quality. For the results of X-Ray examination, see below. Alteration in the voice and tracheal tugging are occasionally to be noted. In aortic incompetence due to syphilis, cardiac asthma is comparatively frequent. Indications of chronic venous congestion supervene in a comparatively small proportion of cases. General oedema is only occasionally met with. As far as my experience goes, there is less tendency for the systolic blood-pressure to rise, and still more so for physical signs of left ventricular hypertrophy to develop, than in the case of aortic incompetence due to other causes. Involvement of the myocardium may reveal itself on polygraphic, and, more frequently, on electro-cardiographic examination, by the presence of auriculo-ventricular block, and rarely by bundle-branch, or intraventricular, block, or paroxysmal auricular fibrillation. For coronary disease and saccular aneurysm, see elsewhere. Subacute bacterial endocarditis may supervene. Sudden death is by no means rare.

The foregoing description covers the great majority of cases. It is necessary to add the following: Relative, and even complete, recovery—either the result of specific treatment or spontaneous—may occur at any period. There may be exacerbations of the disease all through life. Sometimes aortitis escapes notice altogether, and the clinical picture is that of aortic incompetence developing insidiously. The clinical picture may be that of acute general cardiac failure, it may be proceeding to rapid dissolution. Sometimes the condition is only discovered post mortem.

X-Ray examination may reveal general dilatation (Fig. 58), or saccular aneurysm, or both, of the aorta. With regard to the former, as the ascending aorta is most commonly affected, the commonest X-ray finding is increased convexity of the right border of the supra-cardiac vascular shadow just above the right auricle. There may, in addition, be enlargement of the shadow to the left in the region of the aortic knob. Occasionally the descending thoracic aorta is affected. There may be also increased density of the shadow. If

a saccular aneurysm projects mainly backwards, the shadow of the sac, when viewed from the front, may be within that of the aortic shadow itself. In such a case, rotation of the patient to the right or left will enable the observer to separate the shadow of the sac from that of the aorta. In saccular aneurysm, there is usually also some degree of general dilatation. In syphilitic aortitis, there may be also the characteristic changes in the aortic shadow of co-existing atheroma, especially in later life. If there is aortic incompetence, the enlargement of the left ventricle is shown by extension of the heart to the left and increased convexity of the left border, and the latter may exhibit exaggerated pulsation.

In the early stages the Wassermann reaction is almost invariably positive, but as the disease becomes more chronic it is increasingly negative, although

FIG. 58.—Orthodiagram from a case of aortic incompetence, of syphilitic origin. The left ventricle is moderately enlarged, and the aortic shadow is generally enlarged, especially on the right side.

I have been surprised at the frequency with which a positive Wassermann persists even in the case of patients who, clinically, have done well.

Diagnosis.—This is sometimes comparatively easy, but it may be very difficult. The following points, among others, require consideration: The previous history, the age, the history of the present illness, the subjective symptoms, the results of physical and instrumental examination, the Wassermann reaction, the presence or otherwise of syphilitic stigmata, and the course of the disease.

With regard to the previous history, it is very easy to overlook a rheumatic infection in childhood. There may be a history of both rheumatic and syphilitic infection in the same patient. A cardiac lesion coming on in middle life, if antecedent rheumatic infection can undoubtedly be excluded, is strongly suggestive of syphilis, as also is angina pectoris occurring before the age of 40. I would emphasise the importance of pain behind the upper part of the sternum presenting the characteristic features described. If it

has been possible to obtain an accurate history, it will be found that in the vast majority of cases this has been present in the early stages. The pain differs from that of angina pectoris in that its location is higher; it has a far less tendency to radiate to a distance; it is more likely to come on spontaneously, and not to cease completely until after exertion is over; and it is usually much more persistent. The presence of a systolic murmur over the aortic area and an altered second sound in the manner described are of considerable diagnostic importance.

A combination of aortic and mitral valvular disease, especially before 30 years of age, is strongly suggestive of being of rheumatic origin. It is to be noted that sometimes a combined lesion is met with, one due to rheumatic infection and the other of syphilitic origin.

X-Ray examination is of the greatest value in the diagnosis of general dilatation and saccular aneurysm of the aorta due to syphilis. It is necessary to distinguish the former from atheroma of the aorta. This is dealt with on p. 962. A Wassermann test should be done in all doubtful cases. A negative Wassermann is not so valuable as a positive reaction; a single negative reaction does not exclude syphilis; and in some cases it may be advisable to employ a provocative dose of salvarsan or one of the other organic arsenical preparations. We should, on the other hand, be careful not to place too much reliance on the result of the Wassermann reaction; it should be considered in conjunction with other clinical data. A positive Wassermann does not indicate that the patient is necessarily syphilitic; the same applies to the coexistence of other specific stigmata.

Prognosis.—This depends largely upon early diagnosis and the kind of treatment adopted. Taking cases as a whole, the prognosis is very unfavourable, in all probability owing to the fact that a correct diagnosis is not often made until the later stages of the disease. When untreated, the lesion is usually progressive, it may be rapidly so, and the mortality is high. If, on the other hand, a diagnosis is made early, and the treatment is prompt and adequate, especially when the patient has not received specific treatment previously, there is a reasonable prospect of relative recovery, and occasionally recovery is even complete. Naturally the prognosis is much more favourable in the absence of aortic incompetence, involvement of the coronary arteries and of the myocardium, angina pectoris, and aneurysm. Prompt and adequate treatment of aortitis may prevent these occurring. Even in the absence of angina pectoris and aneurysm, in aortic incompetence the prognosis is usually very unfavourable, death often taking place within two or three years after the onset of subjective symptoms. Two important points in all cases are the degree of cardiac failure present, and its rate of advance. Congestive heart failure in syphilitic aortitis is particularly unfavourable, rarely responding to treatment, and it is improbable that such cases will live for more than six months. The results of polygraphic and, still more frequently, electro-cardiographic examination are usually helpful. The presence of pulsus alternans in the absence of a severe grade of tachycardia is an indication of extreme exhaustion of the heart muscle; the occurrence of auriculo-ventricular heart-block is a sign of myocardial involvement; bundle-branch block is usually of very unfavourable significance; and intraventricular block is usually of grave import. A few cases of complete auriculo-ventricular block have been recorded in which energetic

specific treatment appears to have been rewarded with recovery, but as far as my experience is concerned anti-specific treatment is of no avail at this stage. Lastly, in all types of cases, marked and surprising improvement is occasionally met with when adequate specific treatment is adopted.

Treatment.—The various measures which may be applicable to any form of cardiac disorder should be considered in detail. Apart from these, the indication is for anti-specific treatment. This should be adopted in every case in which a definite diagnosis of syphilis of the heart and aorta is arrived at, even if the Wassermann reaction is negative; and in every case of disease of the heart and aorta in which there is a positive Wassermann or other manifestations of active syphilis, even in the absence of clinical evidence that the lesions of the heart and aorta are of specific origin. Cardiac failure is not a contra-indication. It is impossible to exaggerate the importance of the adoption of this method of treatment *promptly*. It should also be *prolonged*. I am a firm believer in the employment of the arsenical preparations—but only under certain conditions. Their indiscriminate use is attended with danger, even of grave degree; they may result in further swelling of the intima of the small vessels, and thus increase the risk of thrombosis. I always recommend a preliminary course, of three weeks' duration, of mercurial inunction and of iodide of potassium by the mouth—10 grains thrice daily during the first week, increased to 15 grains during the second week, and to 20 grains during the third. This to be followed by one of the arsenical compounds administered cautiously, commencing with small doses and only gradually increasing the dosage. The scheme I advise is the result of two or three conversations I have had the privilege of having with Colonel L. W. Harrison, to whom I desire gratefully to acknowledge my indebtedness. This consists of a series of courses of one of the brands of sulpharsphenamine (kharsulphan, metarsenobillon, myosalvarsan, sulfarsenol, or sulphostab), injected deep subcutaneously. The first course makes a cautious start with 10 centigrammes of sulpharsenobenzene, and the dosage is increased, in bi-weekly injections, to 24 centigrammes, the total amount given in the first 54 days being 2·76 grammes in sixteen injections. The reason for cautious dosage of sulpharsphenamine in the first course is that patients with syphilis of the heart or aorta seem easily to be upset at first by arsenobenzene preparations. After the foregoing course of injections, potassium iodide is given for three weeks, to be followed three weeks later by a course of five injections of sulpharsphenamine. This time it may be possible to proceed more boldly with the sulpharsphenamine—three injections of 48 centigrammes and two of 60 centigrammes. Thereafter the treatment is continued with courses of ten injections totalling 5·8 grammes sulfarsenol at intervals increasing from two to five months, with potassium iodide for a month at a time between the courses. Mercury or bismuth should be administered concurrently with the courses of sulpharsphenamine. Mercury is given preferably in the form of weekly intramuscular injections of mercurial cream in a dosage of gr. 1 per injection. Bismuth (see page 208) has very largely supplanted mercury in cases in which the heavy metal is administered by injection, and there are now a very large number of preparations on the market. Generally speaking, the weekly dose should contain from 0·15 to 0·2 grm. metallic bismuth administered at two sittings when an oil-soluble preparation is chosen, and 0·2 to 0·3 grm. administered by one or two in-

jections in the case of a watery or oily suspension of an insoluble compound. Any bismuth preparation can be given either intramuscularly or deep-subcutaneously; the technique is described on pp. 208-210. Similar treatment is continued for two years, after which I suggest a three weeks' course of potassium iodide every two or three months during the rest of the patient's life. It may be advisable to continue anti-syphilitic treatment so long as the Wassermann is positive, even in the absence of other manifestations of active syphilis, for there is a risk of exacerbations all through life, and the small vessels around the principal lesions may become involved.

ANEURYSM OF THE HEART

Aneurysm of the heart may occur in its valves or walls, or in the coronary arteries.

Acute aneurysm of the valves may occur in malignant endocarditis, the semilunar being more commonly affected than the auriculo-ventricular valves. The aneurysm bulges in the direction of the blood current; rupture may take place, giving rise to perforation and valvular incompetence.

Acute aneurysm of the walls of the heart may take place in acute mural malignant endocarditis, usually in the interventricular septum, in the neighbourhood of the undefended space. A diagnosis is scarcely possible.

Chronic aneurysm of the walls of the heart is, in the vast majority of cases, the result of coronary occlusion with infarction of the heart (see page 974), but occasionally is due to fibrosis of the myocardium independent of such, and rarely to traumatism. In the majority of cases the anterior apical portion of the left ventricle is affected, or, less frequently, the aneurysm is found near the base of that chamber, or in the interventricular septum. The aneurysm consists of a sac or localised depression, communicating with one or more chambers of the heart, the size varying from that of a small marble to an orange, or even larger. Its wall is formed of fibrous tissue and muscle-cells, in varying proportion, according to the length of time it has been in existence. Occasionally a certain amount of calcareous matter is present. The aneurysm is lined by thickened endocardium. The pericardium over the affected area is usually adherent. The symptoms of aneurysm are those of general cardiac failure. The area of cardiac impairment may be increased, and occasionally a tumour in the region of the apex may be detected. Sudden death is not of uncommon occurrence, although rupture is comparatively rare.

Aneurysm of a coronary artery is rare and is usually due to atheroma.

WOUNDS OF THE HEART

Wounds of the heart are not of very uncommon occurrence. They may be the result of stabbing, bullet wounds, or the passage of foreign bodies from the œsophagus. Recovery occurs in a fair proportion of cases, especially when due to stabbing. Treatment of these cases is purely surgical.

RUPTURE OF THE HEART

Rupture of the heart is a rare event, and recent observations suggest that in the great majority of cases it is the result of coronary occlusion with infarction of the heart (see above), but occasionally is due to fibrosis of the myocardium independent of such or fatty degeneration of the myocardium, and rarely to traumatism. In the majority of cases the anterior apical portion of the left ventricle is affected, or, less frequently, near the base of that chamber or in the interventricular septum. Rupture of the heart occurs nearly always during physical exertion. It may result in sudden death, or its occurrence may be indicated by sudden agonising pain, intense dyspnœa, pallor, and collapse; in the latter case, the patient may live for some hours or even days.

NEW-GROWTHS OF THE HEART AND PERICARDIUM

Neoplasms may arise from the walls of the heart or from the valves. They, as well as tuberculous deposits, are usually secondary. Primary carcinoma and sarcoma of the pericardium are extremely rare, and secondary deposits are also of unusual occurrence; in the latter case they may be secondary to those of the œsophagus, mediastinal glands, lungs or pleuræ; more rarely from distant parts. Instances of hydatid cysts and actinomycosis of the myocardium and pericardium have occasionally been noted post mortem; they are not diagnosable during life.

The symptoms of new-growths of the pericardium are those of pericarditis, especially of the chronic type, together with the cachexia characteristic of the primary disease. The diagnosis rests upon the recognition of these features, with possibly evidence of malignant disease elsewhere. The prognosis is hopeless, and treatment at the best is only palliative.

FREDERICK W. PRICE.

CONGENITAL HEART DISEASE

Ætiology and Pathology.—Congenital heart disease is more common in males than in females. It may be the result of some developmental defect, or of foetal endocarditis—due to rheumatism or one of the other causes of acute endocarditis affecting the mother during pregnancy. Syphilis is said to be a causal factor. Both developmental defects and foetal endocarditis are more common on the right than on the left side of the heart, as the result of a relatively higher pressure. The pulmonary orifice is more commonly affected than the tricuspid. The lesion of congenital heart disease may give rise to stenosis, or incompetence, or both. The endocarditis is usually of the sclerotic type, although vegetations may occur. It may be noted that there is a predisposition to endocarditis in the foetus the subject of some developmental error, and this increases the primary malformation; endocarditis may also occur after birth.

Varieties.—There are many varieties of this condition, and I shall not

attempt to deal with them all. *As a rule, several lesions coexist, a single lesion being uncommon.*

In ectopia cordis the heart is situated outside the thoracic cavity; it may lie in the neck (ectopia cervicalis), or outside the chest-wall (ectopia pectoralis), or in the abdominal cavity (ectopia abdominalis). In mesocardia the heart occupies the mesial position of the thoracic cavity, the apex-beat being in the epigastrium. In dextro-cardia or dexio-cardia, the heart lies on the right side of the thoracic cavity; this variety of congenital heart disease is usually associated with transposition of the viscera. More or less complete absence of the pericardium is rarely found.

The development of the heart may become arrested at the stage when only an auricle, a ventricle, and a bulbus arteriosus exist, a comparatively rare condition, to which the term "bilocular" heart has been applied. Another comparatively rare form is complete absence of the interventricular septum, in which case the heart consists of two auricles and one ventricle, and is said to be "trilocular." The tricuspid and mitral orifices are usually present, and the bulbus arteriosus is usually divided into a pulmonary artery and an aorta. Another rare condition is complete absence of the interauricular septum, in which case the heart consists of an auricle and two ventricles. One of the most frequent forms of congenital heart disease is an incomplete septum ventriculorum, due to an arrest of development; this is much commoner than complete absence of the septum. The aperture of communication between the two ventricles is usually in the region of the pars membranacea. This condition is frequently associated with pulmonary stenosis or atresia, and hypertrophy of the right ventricle; less frequently with other defects. When coexisting with pulmonary stenosis or atresia, the blood can pass from the right to the left ventricle. When not so associated, the aerated blood after birth passes from the left to the right ventricle, and the walls of both chambers undergo hypertrophy. There may be complete absence of the septum of the ductus arteriosus, or this may be incomplete, with resultant communication between the pulmonary artery and the aorta; in these cases, the right ventricle is generally hypertrophied.

The septum between the auricles may be incomplete, due to arrest of development, and is much commoner than complete absence of the septum. The defect is usually situated at the foramen ovale, due to mal-development of the membrane of the fossa ovalis. It should be noted that the absence of an absolute closure of the foramen ovale is not pathological. The majority of cases of patent foramen ovale are associated with pulmonary stenosis, or a defect in the ventricular septum, or some other congenital defect. Some writers believe that in the larger number of cases a patent foramen ovale results from pulmonary stenosis, while others hold a different view. Whichever view be correct, pulmonary or tricuspid lesions are often found associated with it, and occasionally lesions at the aortic or mitral orifice. In the case of a patent foramen ovale, the blood passes from the right to the left auricle, instead of into the right ventricle and thence to the lungs.

Pulmonary stenosis is perhaps the commonest form of congenital heart disease. A patent interventricular septum is present in the great majority of cases, and a patent foramen ovale is of not infrequent occurrence, while the ductus arteriosus may remain patent. Further, owing to increased pressure in the cavity of the right ventricle, there is sometimes a deviatio

of the interventricular septum to the left ; in this case, the right ventricular cavity is enlarged, and the aorta takes its origin, either completely or partially, from this chamber, the left ventricle being small and atrophied, and communicating with the right ventricular cavity. In pulmonary stenosis the blood accumulates within the right ventricle, and is compelled to take a new channel. If the defect have occurred before the ventricular septum is completed, the septum remains incomplete, and blood passes through the opening and thence to the aorta, the right ventricle being the chief agent in carrying on the systemic circulation. Owing to the increase in pressure in the right heart, the right ventricle and auricle hypertrophy. If the lesion be severe, much of the blood to the lungs must reach them from the aorta through the ductus arteriosus, which does not, therefore, close after birth. If the interventricular septum have completely closed before pulmonary stenosis takes place, the pressure in the right auricle becomes increased ; if the foramen ovale be patent, the blood passes from the right to the left auricle, and in this way a patent foramen ovale is not infrequently found. The right auricle is small and atrophied, and the tricuspid orifice becomes smaller. The cavity of the left ventricle enlarges, and its walls hypertrophy, as it carries on both the systemic and pulmonary circulation. In almost all these cases the blood is carried to the lungs by the patent ductus arteriosus. Thus, the circulation in cases of pulmonary stenosis depends upon the patency of the foramen ovale or interventricular septum, and of the ductus arteriosus. Pulmonary atresia or obliteration of the pulmonary artery is much less common. When complete, and the interventricular septum is closed, the right ventricle is small and atrophied, the right auriculo-ventricular opening ultimately closes, and the heart becomes trilocular.

Stenosis and atresia of the aorta are of much less common occurrence than of the pulmonary artery. Stenosis may exist at one of the following sites : (1) at the orifice, (2) above the entrance of the ductus arteriosus, and (3) just below the entrance of the duct. In the first of these, the ventricular and auricular septa do not close, and the left ventricle remains undeveloped. Most of the systemic circulation is carried on by the pulmonary artery, through the ductus arteriosus. The second, or newborn type, is often associated with other malformations, as, for example, pulmonary stenosis. The ductus arteriosus remains open, and most of the systemic circulation is carried on by the right ventricle, through the duct. The third or adult type of stenosis is more common. By coarctation of the aorta is meant stenosis of the aorta at or just below the junction of the ductus arteriosus with the aorta, *i.e.* in the region of the aortic "isthmus." The condition is more common in males than in females. The ductus arteriosus may remain patent or may close. When the condition is present in adults and in children who have survived the period of infancy, it is supposed to have arisen gradually after birth, in association with the closure of the ductus arteriosus. Usually in such cases an elaborate system of collateral arterial circulation has developed, so that the arterial blood from the upper part of the body—that is to say, from the great arteries given off by the aorta above the site of the obstruction—can pass by enlarged anastomosing branches to the lower part of the trunk and the lower extremities. Hypoplasia of the aorta, or narrowing of the lumen of the vessel throughout its whole extent, with diminished size of the heart, was first described by Virchow, and there is

sometimes accompanying chlorosis. Other malformations of the heart are occasionally also present. The condition known as double aorta is a form of congenital heart disease very rarely found.

Persistence of the ductus arteriosus occurring alone is also a rare condition. It is a common accompaniment of pulmonary stenosis or atresia, when a patent interventricular septum is also present; it may also accompany aortic stenosis or atresia, and congenital disease of the auriculo-ventricular valves. Premature closure of the ductus arteriosus and of the foramen ovale is of rare occurrence.

Transposition of the pulmonary artery and the aorta may be found, the aorta arising from the right ventricle and the pulmonary artery from the left. Among other lesions which may be present are a patent foramen ovale, a patent septum ventriculorum, and a patent ductus arteriosus. Other forms of malposition of the pulmonary artery and of the aorta have been recorded, such as both trunks taking their origin from the left ventricle. A communication between the pulmonary artery and the aorta has been known.

Supernumerary or defective cusps of the cardiac valves have been noted; the number of cusps may be increased or decreased, and in the latter case incompetence of the valves may result.

Congenital lesions of the auriculo-ventricular valves may occur. Stenosis or atresia of the tricuspid or mitral orifice is much less frequent than of the pulmonary artery or of the aorta. A considerable proportion of cases of tricuspid stenosis are congenital. Tricuspid incompetence is rarely congenital; it may be associated with pulmonary atresia. Congenital lesions of the mitral orifice are much rarer than those of the tricuspid orifice.

Symptoms.—The subjective symptoms of congenital heart disease vary in their intensity according to the site and degree of the lesion. It may be laid down as a broad principle that septal defects have a less disturbing effect upon the circulation than stenosis or atresia; indeed, in some of the former cases there may be a complete absence of subjective symptoms throughout the whole course, and the affection is only discovered on physical examination or post mortem. The results of physical examination also vary.

Cyanosis and dyspnoea on exertion are the two chief symptoms. The former may be present within a few weeks of birth, or may only make its appearance after some years. It is a more conspicuous feature of this form of cardiac disease than of any other, the term "*morbus cœruleus*" being, indeed, frequently used for congenital heart disease. This is most marked in the lips, nose, the malar region, and the fingers and toes, being especially noticeable in the nails, and may be confined to these localities, or may be more general. The degree of cyanosis varies up to a deep purple, and is increased by exertion. The lips and nostrils may exhibit thickening, and clubbing of the ungual phalanges of the fingers and toes is usually present, due to chronic venous engorgement. There may be an absence of dyspnoea while at rest, but it may make its appearance on exertion, while in some cases paroxysmal dyspnoea occurs.

While the temperature taken in the mouth or rectum is usually normal, the skin temperature is usually subnormal. The subject of congenital heart disease often complains of feeling cold, is very susceptible to any fall of temperature, and is liable to attacks of bronchitis. On examination the blood is found to have an increased viscosity, and its specific gravity may be as

high as 1070. There is a large increase in the number of the erythrocytes, which may even reach 9,000,000 per c.mm., the hæmoglobin is increased, and may be as high as 160 per cent., while the leucocyte count may show an average of 15,000 per c.mm. There is usually retardation of growth, and in some cases wasting; the mental condition is backward, and the patient is frequently dull and lethargic. There may be syncopal attacks, even resulting in prolonged unconsciousness, while epileptiform attacks may also occur. In certain instances there is a tendency to hæmorrhage from the nose, gums, and less frequently from the lungs. Edema is sometimes present, which at a later stage may become general, and hæmoptysis, hepatic enlargement, albuminuria, and transudation of fluid into the serous sacs may also occur. Not infrequently other bodily malformations are to be noted.

The veins of the retina are almost always dilated and tortuous, the lumina appearing in some places to be unduly wide, and in others abnormally narrow; both arteries and veins are much darker than normal.

The pulse is usually quickened in rate. There is usually evidence of cardiac enlargement, although perhaps not of severe grade, the right side of the heart being particularly affected. Distension or pulsation of the jugular veins may also be present. Sometimes a thrill and frequently a murmur, usually systolic in time, are to be noted. The point of maximum intensity may be over the pulmonary area, but it may be difficult or impossible to define. The murmur is usually rough and grating, and, perhaps, extremely loud; on the other hand, it is sometimes very faint. The pulmonary second sound may be normal, diminished, or loud and ringing.

The subject of congenital heart disease may ultimately die from gradual cardiac failure—the clinical picture resembling that of mitral disease, or infective endocarditis, bronchitis, broncho-pneumonia, pulmonary tuberculosis, one of the acute infective diseases, cerebral thrombosis or abscess, or convulsions, while instances of sudden death have been known to occur.

Passing now to a consideration of the symptomatology of the individual lesions, in dextro-cardia the apex-beat is on the right side of the thorax, and the point of maximum intensity of the aortic second sound is on the left, instead of the right side. For the result of electro-cardiographic examination, see p. 991. When patency of the interventricular septum exists alone, the subjective symptoms are usually slight. A certain amount of dyspnoea and cyanosis on exertion may occur, but cyanosis is not a prominent feature, and there is usually no clubbing of the ungual phalanges of the fingers and toes. There may be evidence of enlargement of the right side of the heart. In some instances a systolic thrill and a loud and harsh murmur over the præcordium are present. Writers also differ in regard to their point of maximum intensity; according to some, *e.g.* Roger, it is in the median line in the upper third of the præcordium, while in the opinion of others it is near to the left margin of the sternum in the third left interspace, or even as low down as the xiphisternum. There is a diversity of opinion also in respect of the question of the direction of selective propagation of the bruit, some believing that there is none, and that the bruit is not audible over the carotid artery, whereas others affirm the opposite. Some writers say that the second sound in the pulmonary area is accentuated. When patency of the interventricular septum is secondary to other lesions, the symptoms of the primary affection predominate.

When patency of the inter-auricular septum exists alone, there is not infrequently an absence of subjective symptoms, and the condition, therefore, may not be discovered during life. In other cases, however, they are present, the results of physical examination then exhibiting considerable variation. A murmur or murmurs may be present over the præcordium, being in some cases systolic, in others diastolic, or, according to some writers, even characteristically presystolic, and having the point of maximum intensity over the base of the heart.

In congenital pulmonary stenosis, cyanosis occurs in the vast majority of cases, and usually within a few weeks of birth, but in rare instances it only makes its appearance after some years. Clubbing of the fingers and other symptoms of congenital heart disease are usually present. The pulse may present no special peculiarity, or it may be small and empty. Sometimes a thrill, systolic in time, and with its point of maximum intensity over the pulmonary area, is present. On percussion the left border of the heart is often, and the right border is almost always, found to be displaced outwards. The most characteristic physical sign is to be found on auscultation; this is a murmur, with its point of maximum intensity in the pulmonary area, systolic in time, usually rough and grating, and, it may be, extremely loud. The murmur may be heard over a considerable area of the chest; occasionally it is quite distinct as high as the first rib; sometimes, indeed, all over the chest. As a rule, it has no direction of selective propagation, and in the vast majority of cases is not audible over the vessels of the neck. The pulmonary second sound is usually diminished or even absent; sometimes there is a pulmonary diastolic bruit, owing to incompetence of the valve.

The physical signs of congenital stenosis at the aortic orifice are the same as those of the acquired form of the disease. In stenosis above the entrance of the ductus arteriosus, cyanosis is usually present, but the physical signs are indefinite; systolic and diastolic bruits may be audible over the front and back of the thorax. In typical cases of the "adult" type of coarctation of the aorta, a number of thickened tortuous arteries can be both seen and felt pulsating beneath the skin of the back and front of the trunk.

When a patent ductus arteriosus occurs alone, there may be no subjective symptoms, or they may be only slight, such as slight cyanosis and dyspnoea on exertion. The area of cardiac impairment is usually displaced to the right, also sometimes to the left, and other evidence of enlargement of the right heart, such as systolic retraction, may also be present. There is sometimes a certain amount of fullness, a thrill, and a murmur, having their point of maximum intensity in the second left intercostal space at least 2 inches from the middle line. The murmur is prolonged, and occupies both systole and diastole; it commences shortly after the beginning of the first sound, and extends into a considerable part of the diastole; indeed, it may persist almost throughout the whole cardiac cycle. It is not propagated to the vessels of the neck. The second sound in the pulmonary area may be accentuated. Other writers have noted the presence of systolic pulsation, a small area of impairment of percussion note, and a shadow on skiagraphic examination.

In congenital lesions at the tricuspid orifice, cyanosis, dyspnoea and clubbing are not conspicuous features, and the latter is not infrequently

entirely absent. The physical signs are the same as those of the acquired form of the disease.

Diagnosis.—While it is usually not difficult to say that congenital heart disease exists, it is a much more difficult task to diagnose the form of the disease, and, further, it should be remembered that several lesions often coexist. In considering the question of diagnosis, the history of the case, the subjective symptoms, the existence or otherwise of evidence of enlargement of the right side of the heart, and the time of occurrence, the point of maximum intensity, and direction of selective propagation of any existing murmur, are all points which should be taken into account. Re-examination may furnish valuable information with regard to both diagnosis and differential diagnosis.

With regard to the diagnostic value of the various symptoms, it may be remarked that cyanosis, even of marked degree, may be present during an attack of acute bronchitis in infancy and early childhood, especially in anæmic and rickety subjects, and also in cretinism; and that clubbing of the fingers may exist in the acquired form of heart disease, more especially in mitral stenosis, while it may be absent in the slighter forms of congenital disease. It is also necessary to point out that in some cases of congenital heart disease the right side of the heart may be only slightly enlarged. The murmurs are usually systolic in time and loud, and their point of maximum intensity and direction of selective propagation are not so typical as those of the acquired form of heart disease. In cases of a non-functional systolic murmur having its point of maximum intensity over the pulmonary area, we should think of the possibility of congenital heart disease. It may, however, be exceedingly difficult, and indeed impossible, to distinguish functional basic murmurs from those of congenital heart disease during infancy and childhood by means of auscultation alone. It should be noted that a prolonged thrill and murmur occupying both systole and diastole may also be met with in arterio-venous aneurysm.

In those subjects of heart disease who have attained to adult life, and even in the case of young children, it is difficult to say whether the lesion is congenital or acquired. If there be a history of marked cyanosis soon after birth, and there have been known to be clubbing of the fingers, evidence of enlargement of the right side of the heart, and a systolic thrill and murmur whose point of maximum intensity and direction of selective propagation are not so typical as those of the acquired form of heart disease present in early life, a positive diagnosis of the congenital form of heart disease is not difficult.

Prognosis.—The prognosis of congenital heart disease exhibits wide variation. If the defect be slight, as, for example, a patent foramen ovale or a small opening in the interventricular septum, a considerable proportion of cases live to an advanced age without experiencing subjective symptoms; whereas if the defect be serious, the duration of life is brief in a large proportion of cases, and, indeed, the individual may die within a few hours. The degree of cyanosis is not absolutely reliable. The occurrence of paroxysms of dyspnoea, syncopal attacks, and convulsions is a very unfavourable omen.

Meso-cardia, dextro-cardia, and absence of the pericardium are conditions compatible with long life. On the other hand, life cannot exist with a bilocular heart. Trilocular heart is compatible with life for some years, and, indeed, instances have been recorded in which individuals have lived

to adult age ; usually, however, the period of life is short. Persons suffering from septal defects not infrequently live to an advanced age. When patency of the interventricular septum occurs alone and the opening is not large, the individual may live to past middle life ; when, however, it occurs in association with other lesions, the prognosis depends upon the latter. The prognosis of an individual suffering from pulmonary stenosis depends upon, besides those points already mentioned, whether there is a patent interventricular septum to afford relief to the over-distended right heart. Death may occur, on the one hand, within a few hours after birth, while, on the other, in the case of lesions of slighter grade, life may be prolonged for 5, 10 or 20 years, and occasionally even to middle life ; indeed, if a patent interventricular septum be present in these slighter lesions, cases have been recorded in which patients have lived to the age of 60. Taking cases of pulmonary stenosis as a whole, however, most of the patients die at an early period of life. Pulmonary atresia is a much more serious condition, and life is prolonged for only a brief period. Cases of stenosis at the aortic orifice do not survive birth, and in those in which stenosis exists above the entrance of the ductus arteriosus life is prolonged at the outside for a few months only, but when just below the entrance of the duct it may be prolonged till middle age. Persistence of the ductus arteriosus is not infrequently compatible with adult life, and individuals have been known to have lived even to old age. Cases of transposition of the pulmonary artery and the aorta do not, as a rule, survive infancy, but instances have been recorded in which these patients have lived to middle age.

Treatment.—The general measures previously laid down are applicable also to this affection. It is particularly important that the patient should be kept warm, and it is imperative that careful and detailed measures should be adopted for the prevention of bronchitis ; if bronchitis should occur, adequate treatment should be adopted without delay. When cardiac failure supervenes, it should be treated on the lines previously laid down.

THE HEART IN HYPERTENSION

Within recent years a good deal of attention has been paid to the heart in hypertension. The subject is of great importance. It is now known that hypertension is one of the most frequent causes of organic disease of the heart in adults ; while cardiac failure, including angina pectoris, is a much more common terminal event in hypertension than is either cerebral hæmorrhage or uræmia.

Ætiology and Pathology.—This is mainly dealt with on pp. 1015–1017. It has been pointed out that hypertrophy of the heart and an increase of the media of the muscular arteries are invariably associated with persistent hypertension. The left side of the heart is very much more involved than the right, and the auricles much less affected than the ventricles. In the course of time, there is a tendency to degeneration in the hypertrophied muscular tissues of the arteries. In the smaller arteries atheromatous, fibrotic, or hyaline degeneration in the intima leads to narrowing and obliteration of the lumen, with resultant ischæmic fibrosis of the organ. There is frequently fibrosis of the myocardium and atheroma of the coronary

arteries; patches of atheroma in the aorta are not uncommon; while the aortic valves are rarely affected. The fibrosis of the myocardium may be due to the increased resistance to the work of the heart having an effect upon its nutrition and removal of waste products; or to the same cause as that of the hypertension; or be of ischæmic origin; or, possibly, the result of degenerative changes in the arterioles of the heart muscle itself; or to a combination of some of these. Sometimes infarction of the myocardium is to be noted. In time dilatation follows hypertrophy, and at necropsy it is usual to find both present.

Symptoms.—The symptoms of hypertension are described on pp. 1044, 1045.

There may be physical signs of hypertrophy of the left ventricle, and accentuation of the second sound and, it may be, a systolic murmur over the aortic area. X-Ray examination reveals hypertrophy of the left ventricle (see p. 902), and there may be, in addition, general dilatation of the aorta

Fig. 59. - Orthodiagram from a case of hypertension, showing great enlargement of the left ventricle, and general widening of the aortic shadow.

(see Fig. 59). The latter is shown by general widening of the supra-cardiac vascular shadow. There may be also increased density of the shadow. The electro-cardiogram almost always indicates preponderance of the left ventricle. In the later stages inversion of the T deflections in lead I is not uncommon. The ventricular complex may be modified in various ways when there is co-existing atheroma of the coronary arteries.

When cardiac failure supervenes, in the early stages the most common symptoms are shortness of breath, palpitation, fatigue and, it may be, pain in the præcordium, on exertion. Angina pectoris is of not infrequent occurrence. Eventually indications of congestive heart failure may supervene. Pulsus alternans and gallop rhythm at the apex are relatively common and important signs in the cardiac failure of hypertension; while cardiac asthma and acute pulmonary oedema are comparatively frequent and characteristic. Often, particularly when there is atheroma of the coronary arteries, the systolic blood-pressure falls, in which event the diastolic pressure may remain relatively high. Increasing dilatation of the

heart is usual, and there may be a systolic murmur at the apex, due to relative incompetence of the mitral valve. The rhythm of the heart is generally regular in the failure of hypertensive heart failure, but auricular fibrillation and, less frequently, auricular flutter are met with in a certain proportion of cases. Lastly, coronary occlusion may occur.

Diagnosis.—The diagnosis of hypertensive heart is easy in the absence of any fall of the raised blood-pressure. When the blood-pressure has fallen with the onset of heart failure, or on account of associated coronary disease, it may present difficulty. In these cases a relatively high diastolic pressure is significant. Gross hypertrophy of the heart in the absence of chronic valvular disease is generally due to hypertension. The results of X-Ray examination of the heart and aorta provide valuable evidence. In this connexion, it is necessary to distinguish between general dilatation of the aorta due to hypertension from that caused by syphilitic mesaortitis. The changes of the aortic shadow in the latter condition are described on pp. 948, 949. Moreover, in atheroma, on account of lengthening with tortuosity of the aorta, localised bulging of any part of the shadow is far less common. Pulsus alternans and gallop rhythm are valuable signs. Ophthalmological examination may show characteristic changes.

Prognosis.—This depends upon the blood-pressure readings, especially the diastolic, the response of the heart to effort, the size of the heart, the condition of the myocardium, of the aorta, the coronary arteries, and of the kidneys, and the degree of any existing cardiac failure. If the state of the myocardium, the aorta, the coronary arteries and the kidneys is good, it is surprising how long the heart is able to support a raised blood-pressure. Pulsus alternans and gallop rhythm are of serious significance; and cardiac asthma and acute pulmonary cedema are usually of grave import.

Treatment.—The treatment of hypertension is dealt with on pp. 1045–1047. When cardiac failure occurs, complete rest in bed for a time, its duration depending upon the degree of the failure, and digitalis are indicated. Venesection may be helpful when there are indications of great distension of the right side of the heart. The various other therapeutic measures, including the question of diuretics, described on pp. 832–847 should be carefully considered.

THE HEART IN HYPERTHYROIDISM

Within recent years, increasing attention has been drawn to the important subject of thyrotoxicosis in relation to heart disease.

It is now known that heart failure may arise not only in typical Graves' disease, but also in middle-aged or elderly subjects who present few, if any, of its symptoms. The degree of damage to the heart in hyperthyroidism seems to depend on the age of the subject and the duration of the thyrotoxicosis rather than on the type of goitre or the severity of the symptoms of hyperthyroidism. The effect of thyroid overactivity on the heart is more serious with advancing age. Enlargement of the heart and heart failure in hyperthyroidism are comparatively infrequent in young subjects, but they become increasingly frequent after the age of 40. The

term "masked," hyperthyroidism has been given to a type of case that is now well recognised. In such, the cardiac symptoms dominate the clinical picture and may even entirely mask any other manifestation of hyperthyroidism. These patients are usually between 45 and 60, and seek medical advice on account of cardiac symptoms. Occasionally the goitre is partly or entirely intra-thoracic. There may be an absence of exophthalmos. The goitre may be insignificant and not noticed by the patient, and it may even be impossible to detect any enlargement of the thyroid. There is little doubt that in the past the thyroid origin of auricular fibrillation and heart failure in such cases has often been overlooked, the condition being attributed to myocardial degeneration.

Among the early cardiological manifestations of hyperthyroidism are persistent tachycardia and changes in the character of the pulse and of the heart beat. The volume of the pulse is increased and the pulse may present a collapsing character owing to general vaso-dilatation. The apex-beat is forcible in character. The systolic blood-pressure is often moderately raised and the diastolic lowered so that the pulse-pressure is increased. It has been shown that the output of the heart rises, involving augmentation of the work of the heart, and consequently the work of the heart is increased. Enlargement of the organ follows. X-Ray examination shows this to affect both sides of the cardiac contour, but often mainly to the left. The pulmonary artery is frequently dilated even in the early stages. Sooner or later persistent auricular fibrillation, or, less frequently, persistent auricular flutter occurs. In some of these cases there are previous paroxysms of fibrillation or of flutter for a period. Extra-systoles and paroxysmal tachycardia are also quite frequent. Later, congestive heart failure is unavoidable. At this stage the heart is often considerably enlarged both to right and left.

In elderly subjects hypertension and arterial disease are commonly found in association with toxic goitre.

Pathology.—The cause of heart failure in hyperthyroidism has not been entirely explained, but probably a number of factors acting in combination account for it.

(1) Increased work of the heart due to the increased circulation rate and tachycardia.

(2) The direct toxic action of thyrotoxin on the myocardium.

(3) Metabolic changes in the myocardium.

(4) The mechanical effect of large goitres which compress the trachea and interfere with respiration.

The last theory has been largely discounted, for in the case of known toxic goitre the heart may remain unaffected. Often when there is severe distortion and compression of the trachea, some authorities deny that hyperthyroidism alone can cause enlargement of the heart, and maintain that such only occurs when there is also hypertension, coronary disease, or some other associated morbid affection.

Pathological hypertrophy and dilatation of the heart are found affecting both sides, but often mainly the left ventricle. In a number of cases, microscopical examination has revealed foci of necrosis, cellular infiltration, or fibrosis in the myocardium, but these lesions are neither constant nor particularly characteristic. It is necessary therefore to regard the enlargement

of the heart as due to increased work and metabolic changes rather than to myocarditis.

Diagnosis.—In the case of typical 'Graves' disease, the recognition of the cardiac affection is easy. In middle-aged or elderly subjects, however, in whom the symptoms have commenced insidiously and the clinical picture is mainly that of heart failure with auricular fibrillation, the diagnosis may be difficult. In every case of auricular fibrillation in which there is an absence of a cardiac lesion, due to antecedent rheumatic infection, the possibility of a thyroid origin should always be borne in mind. A routine examination of the thyroid gland should be made, and also an X-Ray examination for intrathoracic goitre. Loss of weight, a staring expression, sweating, and nervousness should be looked for. Estimation of the basal metabolic rate is valuable, for it is usually raised in thyrotoxic cases with heart failure, unless iodine has been administered. A normal basal metabolic rate, however, does not absolutely exclude a thyrotoxic condition. The response to iodine is often a valuable diagnostic sign, marked improvement being almost pathognomonic of hyperthyroidism.

Prognosis.—The prognosis depends almost entirely on treatment. Provided partial thyroidectomy is performed before the cardiac condition is hopeless, improvement is almost invariable. Those cases with congestive cardiac failure respond very well. In cases of auricular fibrillation, the abnormal rhythm sometimes ceases spontaneously after operation, although such may be delayed to even three to six months. If this does not occur, the administration of quinidine is usually successful. Any existing hypertension, however, usually persists after the operation.

If operative interference is not resorted to, there may be little response to digitalis, even when auricular fibrillation (or auricular flutter) with a rapid ventricular rate is present. Although quinidine not infrequently restores the normal rhythm, if the thyrotoxic state persists, relapse almost invariably recurs. The primary indication, therefore, is to remove it.

Treatment.—The main object is to remove the thyrotoxic condition. This has already been dealt with on pp. 496-499. As far as my experience goes, partial thyroidectomy is the best form of treatment in the vast majority of cases. The presence of congestive cardiac failure, even if of severe degree, or auricular fibrillation is not a contra-indication. Prior to the operation, a preliminary course of iodine should be employed (see pp. 496, 497). Full digitalisation and other therapeutic measures, even the administration of salyrgan, may be indicated. These have been dealt with elsewhere. If after the operation auricular fibrillation does not cease spontaneously, provided there are no contra-indications, the administration of quinidine should be resorted to.

ANGINA PECTORIS

General Considerations.—The subject of angina pectoris is of great practical importance, more especially with regard to diagnosis and treatment. Thus, as far as my experience goes, the malady is overlooked perhaps more frequently than any other cardio-vascular disorder, excepting chronic myocardial disease and perhaps atheroma. Moreover, a large proportion of patients die many years earlier than need be.

At the outset it is of fundamental importance to understand what is meant by the term angina pectoris. Angina pectoris is a syndrome, which may be associated with a diversity of cardio-vascular organic diseases. The syndrome is characterised by a paroxysmal attack of pain in the front of the chest, most commonly in the retro-sternal region, with a tendency to radiate in certain directions; frequently accompanied by a sensation of oppression or constriction; or, occasionally, a sensation of oppression or constriction without pain; if the pain is at all severe it is often accompanied by a sense of anxiety out of proportion to its severity and, if still more severe, sometimes by a sense of impending dissolution—*angor animi*; and the exciting cause of the first attacks is almost invariably physical exertion.

Ætiology, Morbid Anatomy and Pathogenesis.—Heredity is a factor, the chief reason for this being that cardio-vascular degenerative changes are more prone to occur in certain families. The malady is found more particularly in those who are passing from middle into elderly life, and is much more frequent in males than in females. It is much more common in those classes of society who are subject to excessive mental or emotional stress or strain, being relatively uncommon in those whose occupation is of a laborious nature; in which connexion I am of opinion that mental and emotional stress and strain are potent causes of atheroma of the coronary arteries. It is more likely to occur in individuals with an unduly sensitive central nervous system. Other predisposing causes are over-indulgence in food, alcohol, or, perhaps, tobacco; focal sepsis—possibly, especially, chronic cholecystitis; the various forms of chronic rheumatism and gout; hypertension; syphilis; chronic renal disease; metallic poisoning, particularly that due to lead; occasionally it follows one of the acute infective diseases, especially influenza and enteric fever; and, rarely, it is met with in severe anæmia. Taking cases as a whole, syphilis is a relatively infrequent predisposing cause, but in persons under 40 it is an important one.

Among the exciting causes of the attack are physical exertion, emotional excitement, mental effort, cold, such as exposure to a cold atmosphere or a cold wind, and cold sheets, and dyspepsia, particularly attended with distension of the stomach or colon. There may be a combination of two or more factors. Thus, an attack is more likely to occur during physical exertion after a meal. In taking a cold bath there are two factors. An extreme example is hurrying uphill on a cold day against a strong wind and engaging in an excited conversation soon after a heavy meal. Taking cases as a whole, physical exertion is by far the commonest exciting cause, and if a full and accurate history be obtained, it will be found that it is almost always responsible for the first attacks. In the case of physical exertion and, perhaps, still more so, emotional excitement, the first attacks almost always occur *during* the exciting cause, but in the later stages of the malady, not rarely after it. In the case of mental effort, on the other hand, whatever the stage, the attack relatively frequently *follows* the effort.

Angina pectoris occasionally occurs in paroxysmal tachycardia, perhaps even in the absence of organic cardio-vascular disease.

Among the commonest structural changes are atheroma of the coronary arteries; atheroma of the aorta, it may be with general dilatation; chronic myocardial disease, especially fibrosis; syphilitic mesaortitis, it may be with general dilatation or saccular aneurysm; chronic disease of the aortic and,

occasionally, of the mitral valves; and, rarely, chronic adhesive pericarditis. The most frequent of these is atheroma of the coronary arteries. There may be old infarcts in the myocardium.

It is to be observed that angina pectoris rarely affects those with congestive heart failure or auricular fibrillation. Moreover, if either of these supervene in those suffering from angina pectoris, usually no further attacks occur.

The hypotheses which have been advanced as to the actual cause of the attack are numerous, and include the following: That the attack is due to neuralgia of the cardiac nerves; or to cramp, or spasm, of the heart; or to the distension of an enfeebled left ventricle. The late Sir Clifford Allbutt regarded the phenomena as generally, but not always, produced by tension of the first part of the aorta, which is the seat of some inflammatory or degenerative lesion. He described certain rarer cases in which the morbid stress falls on the pericardium. He was of opinion that sudden death, when it occurs, is the result of "vagus inhibition," the shock of the pain causing asystole, associated with myocardial and coronary disease, which is so frequently found in the subjects of angina. Wenckebach believes in the aortic origin of the attack in the majority of cases.

The late Sir James Mackenzie's views were the following: That angina pectoris is an expression of exhaustion of the heart muscle, together with a susceptible nervous system. The pain is a viscerosensory reflex; the sense of constriction a visceromotor reflex, giving rise to spasm of the intercostal muscles. That sudden death is due to the lesion causing the pain, and is frequently the result of ventricular fibrillation.

As far as our present knowledge goes, the most probable explanation of the attack is that it is due to sudden transient inadequacy of the coronary circulation, with consequent ischæmia and anoxæmia of the myocardium. This inadequacy may be the result of structural narrowing of the lumen, or vasomotor spasm, of a coronary artery or of one of its branches. The greater the degree of anoxæmia, the most easily is an attack induced. If the anoxæmia is severe enough, standstill of the ventricles, probably due to ventricular fibrillation, may occur. This theory would also explain the occurrence of angina in aortic incompetency or severe anæmia without coronary disease. In the former, the low diastolic pressure tends to a diminished coronary circulation; and in the latter, the lessened oxygen-carrying power of the blood inclines to anoxæmia of the myocardium.

Recent work on coronary occlusion has an important bearing upon our views regarding the pathogenesis of angina pectoris. Prior to this, one difficulty was that while the pain of angina pectoris is a brief paroxysm, the structural lesions found on post-mortem examination are present both during the pain and apart from it. It follows, therefore, that in correlating pain with a cardio-vascular pathological lesion, a further hypothesis is necessary; for example, arterial spasm, a rise of blood-pressure, or aortic or ventricular distension. Speculation respecting these hypotheses has perhaps deflected attention from the possible fundamental underlying cause of the attack of angina pectoris. In the case of coronary occlusion an acute lesion develops simultaneously with the pain, so that apparently the origin of the latter is not in doubt. When a patient with angina pectoris develops coronary occlusion, it seems reasonable to infer that the paroxysmal pain

preceding the occlusion was due to structural narrowing of the lumen of a coronary artery or of one of its branches.

The transient changes in the electro-cardiograms, which have been observed during attacks of angina (see page 1006), support the ischæmic origin of the attacks.

Notwithstanding the preceding considerations, it should be observed that the precise actual cause of the attack is not at present fully understood. While the ischæmic origin may be accepted in the majority of cases, this does not exclude the possibility of the pain of angina pectoris arising in the aorta, as suggested by the late Sir Clifford Allbutt, in certain cases.

VARIETIES OF ANGINA PECTORIS.—Various methods of classifying angina pectoris are employed by different writers. Among these are the following : (1) Angina minor and angina major ; (2) primary and secondary angina ; (3) true and false or pseudo-angina ; (4) angina of effort and angina at rest—the latter being sometimes called angina decubitus, since it may occur while the patient is in bed ; and (5) angina of effort and angina of coronary occlusion with myocardial infarction.

The first classification, in my opinion, serves no useful purpose. For angina pectoris may range from slight discomfort or oppression or constriction to intense anguish, which may even be fatal ; between these two extremes there is an infinite variety in the severity of the attacks ; there is no approximate line of demarcation between the two forms ; and the same individual may experience attacks of great variation of severity at different times. Respecting the fourth, it is to be observed that individuals the subject of angina at rest almost always also suffer from angina of effort. Regarding the last classification, namely, angina of effort and angina of coronary occlusion, as far as our present knowledge goes, angina at rest may certainly occur apart from coronary occlusion. Moreover, as stated below, there is a fundamental difference between angina pectoris and coronary occlusion.

The best classification is (1) angina associated with organic cardio-vascular disease, and (2) that which is independent of such.

RELATION OF ANGINA PECTORIS AND CORONARY OCCLUSION WITH INFARCTION OF THE HEART : (1) As has been pointed out, in at least half the cases of coronary occlusion there is a previous history of angina pectoris. (2) Angina pectoris occasionally follows coronary occlusion, apparently even a single attack of the latter. (3) The same individual may at one time suffer from angina pectoris and at another from coronary occlusion. (4) Coronary occlusion is a frequent cause of death in the subjects of angina pectoris. (5) It is possible that some cases diagnosed as severe angina pectoris are those of occlusion of a very small branch of a coronary artery.

Notwithstanding the foregoing, I wish to point out and emphasise that there is a fundamental difference, both pathological and clinical, between angina pectoris on the one hand and coronary occlusion with infarction on the other. In the first of these, there is diversity, and in the second, uniformity, of morbid anatomy ; and the clinical features of both are widely different.

Symptoms.—Pain is the cardinal feature of angina pectoris. Its severity may vary from slight discomfort to that of intense anguish. Its locality is most commonly in the retro-sternal region ; next, most frequently across

the front of the chest; rarely in the præcordium, the epigastrium or lower in the abdomen—the so-called angina abdominis, or over a wide area of the back of the chest; or, more rarely, in any of the areas to which pain arising in a more common site may spread (see later). The pain has a tendency to radiate in certain directions; frequently to the left shoulder and armpit; in many cases down the left arm, generally on the ulnar side, usually not beyond the elbow, but it may extend as far as the tips of the ring and little fingers; sometimes both arms; occasionally the right arm only; to near the angle of the scapula, on one or both sides, or to a wide area in the back of the chest; in an upward direction, to the infra-clavicular region, the neck, the jaw, especially the left, the occiput, or even the top of the head; or in a downward direction, to the epigastrium or below. When the locality of the pain is in an area to which that arising in a more common site may spread, it may or may not radiate. As a general rule, the more severe the pain, the more frequently does it radiate and also the wider the radiation. There may be a sensation of oppression or constriction in the chest, and the latter may be so severe that the patient experiences a sensation as if the chest were held in a vice. There may be a sensation of weight or of tingling or numbness in the left arm.

If the patient is in motion, he becomes immobile, and remains so. The expression of the face is anxious. If the pain is at all severe, it is often accompanied by a sense of anxiety out of all proportion to its severity, and, if still more severe, sometimes by a sense of impending dissolution. The skin is often pallid, and there may be a clammy sweat, but occasionally the opposite is the case. There may be flatulence, nausea, occasionally vomiting, and rarely hiccough.

The breathing is usually restricted, and its rate is only infrequently increased. The pulse-rate varies in different cases; in some it is increased, while occasionally it is diminished. There may be irregularity of rhythm, usually due to extra-systoles. The blood-pressure is generally increased to some extent during the attacks.

Transient changes in the electro-cardiogram, similar to those of coronary occlusion during an attack, have been noted in some cases.

As the attack subsides, the patient may belch up a large quantity of air, and it is often followed by the passage of abundant pale urine. After the attack there may be exhaustion, aching in the area of the pain, a sensation of weight, or of tingling or numbness in the left arm, and hyperæsthesia or hyperalgesia over the painful area, even for some time. On the other hand, it is surprising how soon the patient may be free from symptoms, even after a severe attack.

The duration of the attack may vary from a few seconds to a few minutes, or longer, but on the average for a few minutes, and even severe attacks rarely last longer.

In the early stages the attacks may be related only to the more severe forms of physical exertion, and the same applies to other exciting causes; the symptoms may be only mild; the pain may not radiate; the attacks may be very brief; and the symptoms may disappear as soon as the exciting cause ceases. As the malady progresses, the attacks tend to become more and more easily induced, so that they may occur when the patient is walking at the ordinary rate or even slowly on the level, or even during the act of

eating; the symptoms tend to become more severe; more frequently does the pain radiate and also over a wider area; the duration of the attacks is increased; and the symptoms last longer after the exciting cause ceases. Ultimately the attacks may appear to be independent of any obvious exciting cause. In this connexion, however, it is necessary to point out that in at least a considerable proportion of these cases such is really not the case, for, on careful inquiry, it will be found that they occur when the patient is tired, it may be some time after an exciting cause.

On the other hand, the first attacks may be severe; the severity of the attacks may alternate; and the attacks may become less severe and even cease, either as the result of treatment, or spontaneously.

Death may occur during or after an attack, the result of ventricular fibrillation or, less frequently, coronary occlusion.

Diagnosis.—The diagnosis of angina pectoris is of very great importance. It has been pointed out how frequently the malady is overlooked. The diagnosis also frequently presents great difficulties. Nevertheless, if all the avenues of investigation be fully taken advantage of, a correct opinion is possible in the vast majority of cases. The following points, among others, require consideration: the age; the sex; the history of the patient; and the results of examination, this including by the X-Rays and the electro-cardiograph.

The history of the patient's complaint is of pre-eminent importance. It is infinitely more valuable than what is found on clinical or instrumental examination, excepting perhaps the characteristic changes in the electro-cardiogram during an attack if such should be found; indeed, there may be a complete absence of abnormal findings in the subjects of undoubted angina pectoris. It follows, therefore, that a most searching and detailed inquiry of the patient's complaint and from its inception should be made. In this connexion, the characteristic features of the pain and concomitant symptoms, together with the existence and nature of the exciting cause, have been described so fully that all that is needed is to refer the reader to such for his careful consideration. It may be added that in the vast majority of cases, at least in the earlier stages, the symptoms are immediately relieved by nitrites.

With regard to the results of clinical and instrumental examinations, those indicating atheroma of the coronary arteries, atheroma of the aorta, and fibrosis of the myocardium, are the most important. The diagnosis of these conditions are dealt with elsewhere.

For clinical electro-cardiography, see pp. 1002, 1003.

Great difficulty may be experienced when the symptoms are slight and there is an absence of cardio-vascular disease, especially in the former case.

Angina pectoris should be distinguished from indigestion, the ordinary pain of cardiac failure, coronary occlusion with acute cardiac infarction, biliary or renal colic, pleurodynia, intercostal neuralgia, acute pleurisy and cardiac-spasm.

As far as my experience goes, angina pectoris, especially the less severe attacks, is most commonly mistaken for indigestion. There are three main reasons for this: (1) Patients suffering from angina are more likely to get an attack during physical exertion after a meal, and therefore not infrequently

regard the attack as of gastric origin. (2) In angina pectoris, the site of the pain is often in the lower part of the front chest, or epigastrium, or both. (3) As the attack of angina subsides, the patient may belch up a large quantity of wind, with subsequent relief. In the differential diagnosis between angina pectoris and indigestion, *whenever an individual in middle or later life, especially a male, complains of pain in the epigastrium or lower part of the front of the chest after meals, inquiry should invariably be made whether such occurs only, or especially, on exertion after meals; and, moreover, whether he is subject to pain on exertion irrespective of meals.* In indigestion usually the pain does not reach so high, and there is an absence of radiation in certain directions. The response to nitrites and suitable remedies for indigestion respectively is of diagnostic value. The ordinary pain of cardiac failure is, in the great majority of cases, in the præcordium, but it may extend to the left scapular region and down the left arm; it is of a dull aching character; almost always its onset and termination are not sudden; and it is of much longer duration. The differential diagnosis between angina and coronary occlusion is dealt with on pp. 975, 976.

The diagnosis between severe angina pectoris and those cases of biliary colic in which the pain is situated in the epigastrium or lower retro-sternal region may be difficult, especially as the pain of the latter may radiate upwards anteriorly, possibly as high as the neck. In biliary colic, however, the onset and termination are still more sudden; the pain radiates also in other directions characteristic of that malady; there is greater restlessness; there is usually nausea and vomiting; and there is an absence of an exciting cause.

Prognosis.—This is less difficult than formerly, for it is now much more possible to diagnose the nature and severity of the associated cardio-vascular condition. Nevertheless, it is still very difficult, for it exhibits enormous divergence, and one of the characteristic features of the malady is the uncertainty of its outlook. Death may occur during one of the first few attacks; it may take place during what appears to be a mild attack; the attacks may cease for years, and may not recur even after the severest attacks, either as the result of treatment, or spontaneously. The prognosis is not nearly so serious as formerly. Taking cases as a whole, however, it is serious; and each case should be regarded as such until full investigation has been made and time allowed to observe how the case develops, including its response to treatment.

In trying to form a prognosis in any given case, the following points, among others, require consideration: the family history; the ætiology; the frequency and severity of the attacks; how easily they are induced, and the nature of the exciting cause; the nature and severity of the associated, or any existing concomitant, cardio-vascular condition; the degree of any existing cardiac failure; the occupation, the mode of life, and the social condition of the patient; and whether correct and adequate treatment is adopted, and the response to such.

With regard to ætiology, among the most favourable cause is focal sepsis, such as in chronic cholecystitis, which can be removed. Respecting hypertension, it depends mainly upon its degree, the state of the kidneys, and the response to treatment. Hypertension as a cause is not very unfavourable, but, on the other hand, a fatal issue tends to occur earlier than would

be expected, due to some other complication. When chronic valvular or chronic myocardial disease is the result of antecedent acute inflammation, such as acute or subacute rheumatism, the prognosis is much more favourable than when due to primary degenerative processes. When syphilis is the cause, the prognosis depends upon the response to treatment. This is usually very unfavourable. In this connexion, however, it is important to note that I do not regard the pain in the early stages of aortitis, i.e. before involvement of the coronary arteries or the aortic valves, described at the bottom of page 947 and top of page 948, as that of angina pectoris. Naturally, the more severe and frequent the attacks, and, if increasing, the more unfavourable the outlook. The same applies to the ease with which they are provoked, and if they occur while the patient is at rest, or during sleep. When emotion is the exciting cause, the prognosis is more favourable than in the case of physical exertion, and the same applies when there is a susceptible nervous system, for both afford opportunities for successful treatment. The nature and severity of the associated cardio-vascular organic disease is perhaps the most important consideration of all. The prognosis of these is fully dealt with under the respective diseases. In this connexion I would emphasise the value of X-Ray and electro-cardiographic examinations, especially the latter. Fatty infiltration is among the most favourable associated conditions, while coronary disease is the most serious, and fibrosis of the myocardium probably ranks next in importance. The occupation, the mode of life, and the social condition of the patient are also of cardinal importance. The question is whether in future it will be possible for the patient to live within the limits of his diminished cardiac strength and, in addition, to avoid what he has found by experience to be the exciting cause of the attacks. The importance of correct and adequate treatment, and the response thereto, is obvious.

Treatment.—The treatment of angina pectoris is of the utmost importance. In this connexion it has been pointed out that a large proportion of patients die many years earlier than need be.

Treatment resolves itself into two parts: A. Treatment of an attack; B. The prevention of the recurrence of the attacks.

A. *Treatment of an attack.*—The patient should be warned to remain still and, as far as possible, place himself in the position he finds by experience affords him most relief. In the majority of cases the most efficacious and suitable remedies are the nitrites. Those most frequently used are amyl nitrite (2-5 minims or more), nitroglycerine ($\frac{2}{100}$ th- $\frac{1}{50}$ th gr. or more), sodium nitrite ($\frac{1}{2}$ -2 grs. or more) and erythrol nitras ($\frac{1}{2}$ -1 gr. or more). The rapidity of action of the respective drugs is in the order in which they are placed, and the duration of such inversely so. Amyl nitrite is usually the most potent; but nitroglycerine is sometimes so, and is often to be preferred apart from this because of its convenience, and also it is less likely to cause any disagreeable effects. Amyl nitrite is inhaled from a glass capsule covered with silk which is broken. Nitroglycerine may be administered in the form of tablets, which should be chewed, or placed beneath the tongue, instead of being swallowed immediately; or liq. nitroglycerini, 1 per cent., in a little water. Care should be taken that the preparations are fresh and can be easily used by the patient, i.e. that the box containing the amyl nitrite can be opened and also the capsules broken easily, and that the tablets of

nitroglycerine are not hard. The dose of amyl nitrite or nitroglycerine should be sufficient to ensure complete relief without inducing any disagreeable symptoms; and it may be necessary to repeat the dose. The effect of these remedies is sometimes enhanced by a dose of a diffusible stimulant or, if there is gastro-intestinal flatulence, of a carminative mixture. The patient should invariably carry about with him the foregoing, with instructions under what circumstances and how they should be used. Sodium nitrite and erythrol nitras are much more useful for prophylactic purposes. If amyl nitrite and nitroglycerine fail, morphine hypodermically ($\frac{1}{4}$ – $\frac{1}{2}$ rd gr. or more) is indicated. Nitroglycerine hypodermically may be combined with the morphine. Failing these, the inhalation of chloroform, cautiously administered, may be tried. If the drugs enumerated are not at hand, hot drinks, alcohol, or sp. ammon. aromat., or the application of heat over the area of the pain may be helpful. When there is collapse, cyanosis, or cardiac asthma, suitable measures should be adopted.

I would point out, and strongly emphasise, that after an attack of angina, however mild, the patient should have a period of rest (see later). I have seen a number of deaths occur because patients have got up the next day or soon after an attack of some severity.

B. *The prevention of the recurrence of the attacks.*—The ætiology should be reviewed, with the object of treating the primary cause, such as focal sepsis, hypertension, syphilis, or severe anæmia.

Secondly, any associated cardio-vascular organic disease and concomitant morbid affection should be considered.

In the next place, detailed investigation of the patient's occupation, general mode of life, habits, hours in bed, and the amount and character of his sleep, how long he takes off for his meals, his mental character, and of the history of the attacks, including the exciting cause, should be made.

Having done this, I would ask my readers carefully to consider the various therapeutic measures which may be applicable to any form of cardiac disorder recommended on pages 832–847.

If there is tiredness or exhaustion of the heart or nervous system, a period of rest, both physical and mental, is strongly indicated. The amount varies according to the degree of tiredness or exhaustion. In severe cases, at least some weeks, and it may be some months, of complete rest, followed by a period of partial rest, may be required.

There is no other cardiac malady in which it is so necessary for a patient to live within the limits of the heart's strength as in angina pectoris; for the attacks are much more likely to occur when there is tiredness or exhaustion of the heart or of the nervous system. It is, therefore, of the utmost importance that he should constantly do this—indeed, the ideal is to keep something in reserve. With regard to the amount of physical exertion which he may undertake, the cardinal principle is that it should not be attended or followed by an attack, or any other abnormal subjective symptoms; while, on the other hand, any exertion short of inducing such is permissible, the best form being walking. The importance of attending to the amount of mental work is not sufficiently appreciated. It is advisable that he should not engage in physical exertion soon after a meal, or against a strong or cold wind, and the first also applies to mental effort.

All excitement, worry and other forms of emotional stress and strain

should be avoided. The patient should be in bed long enough each night—at least nine hours—and take at least an hour off for lunch, resting after finishing eating. A sufficient amount of holidays, of a restful nature, is enjoined.

Wool should be worn next to the skin. Cold rooms, cold sheets at night, and hot and cold baths are contra-indicated. A mild climate and a non-hilly locality are indicated.

The patient should eat slowly and thoroughly masticate his food. What fluid is taken with meals to be drunk at the end of the meal, and the less the better, the rest being taken between, and preferably an hour before, meals. Articles of diet which tend to cause dyspepsia, particularly that form which is accompanied by flatulent distension of the stomach or colon, over-indulgence in food, alcohol, tobacco, coffee or tea, constipation, and straining at stool, are to be avoided.

It is exceedingly important that the patient should avoid anything which he has found by experience likely to induce an attack.

If the patient suffers from an unduly excitable nervous system, or is prone to worry or be anxious, sedatives are often exceedingly helpful. (See page 833.) Among the best of these is luminal, commencing with $\frac{1}{4}$ – $\frac{1}{2}$ gr., four or three times daily, and gradually reducing to the minimal daily dose, which may be increased at any time, if and as required. If there should be any defect in the amount or character of sleep, this should be adequately treated.

Massage, provided it stops short of inducing any abnormal symptoms, is often helpful in patients who cannot take enough exercise to keep them in good physical condition, and during the latter part of the time that he may be confined to bed.

Periodic courses of nitrites, or iodide of potassium (5–20 grs., with sp. aromat. ammon.), or alternating them, should be tried, especially if hypertension is present, but even apart from this. Large doses of diuretin, theobromine, theophyllin, and theominal are sometimes helpful. The last is a combination of 5 grs. of theobromine and $\frac{1}{2}$ gr. of luminal, and is often better than one of the other drugs alone.

It has recently been suggested that treatment by insulin and glucose is of value in angina pectoris. There is atheroma of the coronary arteries in the great majority of cases, which must lead to impairment of myocardial nutrition. If, as seems likely, metabolic derangement in the myocardium contributes to the production of anginal pain, the application of glucose-insulin therapy should be of benefit. Five units of insulin subcutaneously, followed in fifteen minutes by 50 grammes of glucose by the mouth, is given once daily. This may be continued for one or some weeks. Although beneficial results have been reported by several workers, as yet there are insufficient data to determine the value of this method of treatment and also the special indications for its use.

Recently X Rays therapy and diathermy have been tried, and they certainly deserve further investigation.

Nitroglycerine ($\frac{1}{300}$ th– $\frac{1}{100}$ th gr.) may be tried as a prophylactic measure a few minutes before engaging in reasonably necessary physical exertion; and sodium nitrite, erythrol nitras or theominal at bedtime when the patient is subject to nocturnal attacks.

Within recent years operative treatment has been resorted to for the relief

of very severe pain. T. Jonnesco, in 1916, removed the last two cervical ganglia and the first dorsal ganglion of the sympathetic on the left side. Since then other varieties of surgical-sympathectomy have been performed as well as cutting the depressor nerve, dorsal sympathectomy and para-vertebral injection of alcohol. In my opinion, in the present stage of our knowledge, surgical measures are inadvisable. The choice of case is exceedingly difficult. As pointed out by Mackenzie, when there is organic disease of the heart, the coronary arteries, or the aorta, the pain is a protective symptom, and its removal is fraught with danger.

CORONARY OCCLUSION WITH ACUTE INFARCTION OF THE HEART

Ætiology and Pathology.—It has been pointed out on page 923 that if complete and abrupt occlusion of a coronary artery, or of one of its main branches, occurs, acute infarction of the heart may ensue.

Acute infarction of the heart occurs most frequently in those who are passing from middle to elderly life, and is much more common in males than in females. Atheroma is a much more frequent cause than chronic arteritis. It is rarely due to embolism, which is relatively more common in those who are younger. Not infrequently there is a history of hypertension. The general consensus of opinion is that in about half the cases there is a previous history of angina pectoris. In my opinion, if a full and accurate history were obtained in all cases, the percentage would be materially higher.

The anterior apical portion of the left ventricle and the adjacent part of the interventricular septum is the most frequently affected. A mural thrombus on the inner surface of the infarct is of frequent occurrence. This may give rise to embolism in the brain, kidneys, spleen, intestines, limbs or elsewhere. If the infarct extends to the pericardium, fibrinous pericarditis results.

The infarct is gradually replaced by fibrous tissue. Rupture of the heart at the site of the infarct may take place at once, with resultant hæmo-pericardium; or an aneurysm may develop, which later on may rupture; or there may merely be a fibrous scar.

Symptoms.—The most common and prominent symptoms are pain, dyspnoea, shock and collapse at the onset, especially pain, and perhaps nausea and vomiting.

The pain is not related to any exciting cause. Its onset is usually sudden. The site of the pain is the same as that of angina pectoris (see pp. 967, 968), except that almost certainly it is relatively more frequent in the epigastrium. The pain may be localised, or may radiate in certain directions, as in the case of angina pectoris, though probably less frequently so. There is usually severe pain; but, on the other hand, there may be merely slight discomfort, or a sensation of oppression, or moderate pain, or pain amounting even to intense anguish. The pain usually persists, it may be for hours or even days—*status anginosus*. There may be *angor animi*. When the pain is in the epigastrium, there is often abdominal distension. Unlike angina pectoris, the patient is restless, and may not be able to refrain from walking

about; and the pain is not relieved by rest, or by vaso-dilators, and may even be increased by the latter.

Dyspnoea is present in the vast majority of cases. It is usually severe, but may vary from that of slight degree to that of cardiac asthma. Sometimes Cheyne-Stokes' respiration and, rarely, acute pulmonary oedema, is present. At the onset there may be symptoms of shock and collapse. In these cases there is an ashen pallor, profuse cold sweating, and a rapid feeble pulse. When there is nausea and vomiting, it is usually at the onset, but they may occur later on.

The blood-pressure almost invariably falls, usually considerably, and it may be markedly so, and frequently continues to do so, and rapidly. The pulse-rate varies considerably. It is usually increased in frequency, it may be to 100, 120 or more, which may persist, but occasionally it is not increased, and rarely is there bradycardia, even pronounced, in each case in the absence of an abnormal rhythm. It is of smaller amplitude, and weaker. Extrasystoles, or, less frequently, paroxysmal or persistent auricular fibrillation or auricular flutter, paroxysmal tachycardia, or auriculo-ventricular block may occur. The apex-beat is usually diminished and may be absent. The cardiac sounds are generally diminished, especially the first at the apex, which may be very faint, and may also be short, sharp and clear, resembling the second sound. Sometimes a tic-tac rhythm or, perhaps less frequently, a gallop rhythm may be present. The transverse measurement of cardiac impairment becomes increased, usually considerably, and it may be remarkably so, and the dilatation is generally rapid. A mitral, and a tricuspid, systolic bruit may develop—due to relative incompetence of the valves. Localised pericardial friction, which may be very transient in the area of the infarct, may sometimes be noted, and, if so, is of great diagnostic importance.

Slight or moderate pyrexia is usual during the first few days, and may occur within the first few hours. There is often a moderate leucocytosis, the polynuclear cells being relatively increased in number.

Chronic venous congestion and oedema of the lungs and systemic venous congestion may develop. Embolism (see page 974) may occur.

The foregoing is a description of the clinical features of a typical case. It is to be noted, however, that the clinical picture varies considerably in different cases. Thus: Pain may not be the most prominent symptom, and there may be merely slight discomfort or slight oppression, or even a complete absence of abnormal sensations, in the front of the chest. In such cases, dyspnoea may be the most prominent symptom. There may be acute pulmonary congestion and oedema. There may be rapid pulmonary congestion and oedema and systemic venous congestion. Shock and collapse may be the most prominent symptoms. The clinical picture may resemble that of an acute abdominal condition, especially if embolism in the abdomen has occurred. Lastly, the symptoms may develop insidiously.

For the results of electro-cardiographic examination, see pp. 1003–1006.

Diagnosis.—A correct diagnosis is practically always possible from the clinical features just described, together with the results of electro-cardiographic examination; indeed, in the great majority of cases, it may be made from a careful consideration of the first alone. The diagnostic value of the electro-cardiograms is discussed on pages 1005, 1006.

Coronary occlusion should be differentiated from angina pectoris; the

rupture of the saccular aneurysm of the thoracic aorta; ordinary cardiac failure accompanied by pain; in those cases in which dyspnoea is the most prominent symptom from cardiac asthma due to other varieties of heart disease; from auricular fibrillation with a rapid ventricular rate in which the patients become very ill within a few hours of the onset of the abnormal rhythm; and from perforation by a gastric or duodenal ulcer, biliary colic, acute pancreatitis, and other abdominal emergencies.

The distinguishing features between coronary occlusion and angina pectoris are that in the former the pain is not related to any exciting cause, is of longer duration, is accompanied by restlessness, and is not relieved by vaso-dilators; there is usually severe dyspnoea; there is generally shock and collapse, and often profuse sweating; vomiting is of frequent occurrence; the pulse, and especially the blood-pressure, the cardiac sounds and sometimes the cardiac rhythm are very different; pericarditis, pyrexia, leucocytosis and embolism may occur; and congestive heart failure frequently develops.

Coronary occlusion and acute abdominal conditions are more likely to be confused when in the former the locality of the pain is in the abdomen, and especially if embolism in the abdomen has supervened. The age and, especially, the sex should be taken into consideration. The previous history is perhaps most important of all. In coronary occlusion the patient has usually suffered from angina pectoris, while in acute abdominal conditions the history points to abdominal disease. In acute abdominal conditions the pain generally does not reach so high, and there is an absence of radiation in certain directions. Severe dyspnoea and marked tachycardia suggest a cardiac origin. The results of the examination of the heart and of the abdomen respectively are of notable assistance.

Lastly, in the differential diagnosis of coronary occlusion from any other malady, the results of electro-cardiographic examination are usually of great value (see pp. 1005, 1006).

Course and Prognosis.—These exhibit a very wide variation in different cases. It would appear that about half the patients in whom a definite diagnosis of coronary occlusion has been made die. Death may occur within a few minutes or a few hours. If the patient lives for a few days or, still more so, for a week, he may die within a few weeks or a few months, usually from congestive heart failure, or from some complication, but more frequently he survives. In the latter event, progress is generally very slow, and as a rule the patient has to live a very restricted life, although rarely recovery is almost complete. Subsequent attacks may occur. Angina pectoris occasionally follows coronary occlusion. On the other hand, if the patient previously suffered from that malady, he is less likely to have attacks in future.

In trying to form a prognosis, the following should be taken into account: The severity or degree, and the duration of, any existing pain, dyspnoea, shock and collapse, fall in blood-pressure, tachycardia, modification of the cardiac sounds or rhythm, pyrexia, leucocytosis and congestive cardiac failure. Treatment also has an important bearing upon the outlook.

Treatment.—I am firmly of opinion that whenever a definite diagnosis of coronary occlusion has been made, at least three months complete rest, physical and mental, followed by a similar period of partial rest, is strongly indicated; and that in severe cases the duration should be longer. In the early stages the more absolute the rest and tranquillity of mind the better.

Great care should be taken regarding movement of the bowels; death may take place during the act of defæcation. The bowels need not be moved for the first 48 hours. They should be opened by means of enemata. Warmth to the body, and stimulating liquid or semi-solid, nutritious food are indicated. Glucose, which may be administered intravenously, is useful for collapse. For the pain, morphine hypodermically, in sufficient dose and frequency, and for as long as is found to be required. Nitrites are contra-indicated. Later, milder sedatives may be very helpful to ensure a sufficient amount of sleep and for restlessness. Digitalis is indicated in congestive cardiac failure, but caution should be exercised and large doses avoided. The treatment of auricular fibrillation and of auricular flutter is dealt with elsewhere. Quinidine, as described in the upper part of p. 840, has proved successful in some cases of paroxysmal tachycardia, perhaps especially of ventricular origin, complicating coronary occlusion.

The greatest care should be exercised during convalescence. During the last few weeks that the patient is in bed, his back may be gradually raised by means of pillows. Afterwards, he is moved to a couch, at first only every other day, for at least four weeks. After the first two weeks of this time massage, at first very gently and for short periods only, and gradually increased, *may be tried*. Later on, slight walking exercises may be permitted. If during any stage there are abnormal subjective symptoms, or lowering of blood-pressure, or maintained increased frequency of the pulse, it means that the amount of exertion is too much and should be correspondingly reduced.

The patient should be impressed with the importance of living not only within the limits of his diminished cardiac strength, but even keeping something in reserve, during the rest of his life.

PRIMARY CARDIAC OVERSTRAIN

Definition.—By primary cardiac overstrain is meant a cardiac disorder which is the immediate result of excessive physical exertion in an individual whose heart has been sound, or in whom the heart has been already somewhat impaired. It formerly included the condition known as “soldier’s heart” or the “irritable heart of soldiers,” which I shall describe separately.

Ætiology.—The affection is the direct result of excessive physical exertion, and is most frequently met with in persons of athletic habits and in soldiers. It is more apt to occur in those who undergo excessive physical exertion while not in training; indeed, it is questioned by some whether the affection can occur in persons with previously sound hearts who have been properly trained. It is also more likely to occur in older persons, and where there is a history of rheumatism or of some other acute infection, in anæmia, and in those who have indulged in excesses of any kind.

Symptoms.—When the malady is due to sudden physical strain, as in boat-racing or Alpine climbing, there may be lividity or cyanosis of the face, giddiness, faintness, passing into actual syncope, together with vomiting and even fatal syncope, and possibly evidence of acute dilatation of the right heart. Later on, there may be collapse, cyanosis, coldness of the skin, precordial uneasiness and even actual pain, quick and shallow respiration, and a quickened, small and thready pulse; while later, in severe cases, there

may be evidence of œdema of the lungs. These acute symptoms may be followed by general lassitude, impaired digestive functions, an increase of rectal temperature, and a pulse of subnormal pressure, although at the same time the apex-beat may be forcible and tumultuous; tachycardia, and a forcible and tumultuous apex-beat being especially noticeable on the least exertion. For some weeks, dyspnœa and an increase of cardiac rate from 30 to 40 per minute above the normal on even slight physical exertion, nervousness, languor, and a sense of fatigue on mental exertion are apt to occur.

In the chronic form of the affection, among the symptoms are palpitation, even of severe degree, a feeling of oppression or of constriction of the chest, and sometimes actual pain over the præcordium, extending to the left shoulder, and occasionally down the arm; as a rule there is no sense of impending death. Among other symptoms which may be noted are dyspnœa and faintness on exertion, tremors, nervousness, insomnia, noises in the ears, flashes of light before the eyes, vertigo, a dull headache, hebetude, and languor, while the digestive functions are often impaired. There may be some degree of cyanosis. These symptoms may pass away with rest, only to reappear on exertion. The pulse-rate is usually increased, but is rarely over 120 per minute while at rest, although exertion causes a further increase—up to as much as 140 or 150. The pulse is usually small, weak, and of subnormal pressure, while the apex-beat may be diffuse and diminished in force or even absent, but on exertion may become unduly forcible and tumultuous. The area of cardiac impairment is usually increased to the left, and not infrequently also to the right. The cardiac sounds may be feeble, or short and sharp, and may be reduplicated, or a mitral or tricuspid systolic murmur may be audible, while the second sound in the pulmonary area may be accentuated.

Diagnosis.—The diagnosis in large measure resolves itself into the question whether the case is one of primary cardiac overstrain, or whether the heart has been previously damaged; in the latter case, excessive physical exertion is merely the exciting cause. In considering this problem, the presence or absence of a previous history of one of the acute infections and the state of the general health, and whether there is evidence or otherwise of myocardial, valvular, or arterial disease, are points of material importance.

Prognosis.—The prognosis of primary cardiac overstrain exhibits a wide variation, ranging from a slight illness on the one hand to a severe and even irremediable affection on the other. In the less severe degree of acute cases occurring in the young and previously sound and vigorous, recovery is the rule; the patient may be well in a few days or weeks, although, on the other hand, progress may be slow, and a long time may elapse before the individual is capable of an ordinary amount of work. If tricuspid regurgitation be present, this, unlike mitral regurgitation, usually passes off quickly. But if the heart has been previously affected by rheumatism or by some other infection, and in the case of older persons, the prognosis is serious; recovery may be long delayed, or the patient may be always compelled to lead a sedentary life, and, in some cases, even a fatal termination may result. In all cases of primary cardiac overstrain a diminishing increase of pulse-rate on exertion is of favourable omen.

Treatment.—In the acute cases, a very hot bath is to be commended,

the patient being lifted out of it in a blanket, or a hot pack, together with the administration of one or two 15-grain doses of diuretin. A strictly limited amount of food, both solid and liquid, is indicated in the early stages, and no tea, coffee, alcohol, or tobacco. Oxygen may be required in some cases; morphine and strychnine are rarely necessary. Later on, tea and coffee may be allowed in limited quantities, but the patient should still abstain from alcohol and tobacco. The bromides are often extremely useful in persons who suffer from an unduly excitable nervous system or from insomnia. When the patient is able to get up, extreme caution should be enjoined as to the amount and character of any exertion. The use of electricity is contra-indicated. Warm baths, followed by a cold douche, may in individual cases be tried, if followed by a reaction. Such general tonics as iron, arsenic, and quinine may be indicated.

In the more severe or chronic cases, prolonged physical and mental rest may be necessary, although massage may be employed at an early stage with advantage, provided it is at first very gentle and at all times stops short of causing fatigue. The diet should be small in quantity, nutritious, and easily digestible, and if atonic dyspepsia be present it should be treated.

SOLDIER'S HEART

Synonyms.—The Irritable Heart of Soldiers; Disordered Action of the Heart (D.A.H.); Effort Syndrome.

This condition was first fully described by Da Costa in 1862 and later, and by Myers in 1870. It is necessary to point out, however, that in the light of recent discoveries some of the cases described by these writers were in all probability cases of auricular fibrillation, the onset of the latter condition having in many cases been associated with undue physical exertion. Since the Great War much attention has been paid to the subject, owing to the large number of cases which have arisen, apparently as a result of the conditions attendant upon the life of the soldier in modern warfare.

Ætiology and Pathology.—The affection is more common in those of sedentary occupation, and there is frequently a history of acute rheumatism.

The prevailing view prior to the Great War was that the malady was due either to the accoutrements of the soldier, such as tight belts and closely fitting uniforms, or to over-exertion, such as "setting-up drill." It may be pointed out, however, that in a discussion reported in the *Journal of the Royal Army Medical Corps*, 1910, R. J. S. Simpson pointed out that the method of training can only be subsidiary as a cause, and expressed the belief that the affection is congenital, or at least developmental; while W. Bezley Thorne put forward the view that it depends upon toxæmia, and recommended the removal of this condition as part of the treatment. Speaking broadly, investigations conducted during and after the Great War appear to show that in a large proportion of the cases of soldiers invalided home for so-called soldier's heart affections, the heart is not the *fons et origo* of the malady, and that the circulatory symptoms are but a manifestation of the general state. On inquiry, it has been found that in many of the cases there has been a history of some slight illness, such as diarrhoea, or a febrile attack pointing to some infection.

Among the hypotheses which have been advanced in explanation of the condition are the following :

1. *Glandular*.—The glands blamed are the thyroid and the suprarenals. Some consider that the condition is one of hyperthyroidism, and state that enlargement of the thyroid is present in nearly every case. But as Lewis found this in only 4 per cent. of the cases, and other observers have scarcely ever noticed it or other signs of hyperthyroidism, this theory cannot be said to be proved. The irritation of the sympathetic, with its concomitant results, noted in the condition, has led some to blame the suprarenals ; but it is difficult to believe that this is the true cause, especially as the administration of adrenaline appears to aggravate the condition.

2. *Nervous system*.—All the symptoms point to the nervous system as bearing the full force of the blow ; it is not, however, the primary but the secondary factor, the exciting cause falling chiefly on this system.

3. *Myocardial factor*.—It has been suggested that, as a history of rheumatic fever is so frequent, the myocardium is chiefly to blame. Rather does it seem that the myocardium is affected secondarily by the exciting cause.

4. *Bacteriæmia*.—At one time this was thought to be the cause of the disease, but the failure of Dimond and Briscoe to find the presence of any bacteria in the blood has disposed of this claim.

5. *Poisoning following some microbic invasion*.—Numerous authorities subscribe to this view, as in 50 to 60 per cent. of cases the symptoms have been first noted after an infection. I do not consider, however, that a case has been made out in support of this view. It may be asked, for example, what about the other 40 per cent. in whom there is no such history, and why should infection cause soldier's heart in one case and not in another ?

Personally, I consider that the view of Simpson and others, namely, that the malady is congenital, or at least developmental, has much to commend it. One person is constitutionally not so strong as another (called by some "constitutional inferiority"), the reason of which cannot be discovered. This view would explain why alteration of accoutrements and avoidance of over-exertion do not obviate the condition. I incline to the view that numerous factors play a part in the production of the malady, and that the following may explain the pathology : As in the case of civilians, one soldier is constitutionally not so strong as another, as a result of congenital or developmental weakness, and any evil effect weakening the system by infection, fright, shock, or emotion of any kind, overstrain, or other concomitants of warfare, will in those soldiers less able to bear these produce the symptoms of soldier's heart, while their stronger brethren will escape ; especially will this be the case in those who before enlistment have been employed in sedentary occupations. During the pre-war period the condition may have remained latent, as there had not been a sufficient excitement to make it evident ; but directly this is increased by the conditions of warfare the system breaks down.

It may be added that soldier's heart in no way differs from what may be met with in civilian life.

Symptoms.—Thanks to Lewis and other workers, the individual symptoms have received thorough investigation, but nothing of any importance has been added to the symptomatology since the classic description given by Da Costa. Among the commonest symptoms complained of are

invariably breathlessness; almost always a sense of exhaustion after effort, physical or mental, giddiness and headache; frequently palpitation, præcordial discomfort or pain, depression of spirits, and irritability of temper, and less commonly fainting attacks, nervousness, loss of emotional control, lack of power of concentration, impairment of memory, sleeplessness, disagreeable dreams, tremors of the hands, and vasomotor symptoms, such as flushing, and numbness, coldness, and pallor or lividity of the extremities. Shortness of breath is usually related to exertion or emotion, being out of proportion to either, and the respiratory rate may rise to 40 or even 70 per minute. The respiratory rate is always normal while asleep, and usually so apart from physical exertion and emotion. The sense of exhaustion after effort may be extreme. Giddiness is associated with physical exertion or with change of posture, especially the latter; as also are fainting attacks, which may be accompanied by loss of consciousness. Headache usually occurs after exertion, and may be severe, throbbing and localised in the frontal region. Palpitation is generally induced by physical exertion or emotion, but it may be nocturnal, and occasionally occurs apart from these. Pain is usually related to exertion, less frequently to emotion, and is occasionally nocturnal. It is commonly limited to the præcordium, but sometimes radiates to the back, to the neck, or down the left arm. The cardiac rate is increased, and also the increase in rate on physical exertion, emotion, and the assumption of the upright posture after lying down is in excess of the normal, as is also the time which elapses before the pulse-rate returns to its rate prior to exertion. The blood-pressure is usually not increased, but the increase on physical exertion and as a result of emotion is exaggerated. The apex-beat is often unduly visible and palpable, but it is not heaving in character. On X-Ray examination, the heart is not found to be enlarged. Not infrequently the first sound is shortened and sharp, and the second sound at the apex accentuated. A systolic murmur is sometimes audible, often having its point of maximum intensity in the pulmonary area. There is nothing abnormal revealed on electro-cardiographic examination. The deep reflexes are usually exaggerated. There is a moderate leucocytosis, the lymphocytes being relatively increased in number.

Diagnosis.—There are certain fundamental distinctions between primary cardiac overstrain and "soldier's heart." In the latter, the sense of exhaustion after effort is more prominent; giddiness and fainting attacks are more associated with change of posture and less with physical exertion; and there is much more likely to be depression of spirits and other nervous symptoms, as well as vasomotor symptoms. It is necessary to diagnose the condition from cardiac hypertrophy; in the latter, the apex-thrust is slower and longer than normal, and the first sound is long, low in pitch, and muffled.

Prognosis.—This is, generally speaking, not good, from the point of view of complete recovery, a majority not being able to return to their occupation.

Treatment.—*Prophylactic.*—Slow and carefully graduated training is especially advisable in recruits whose occupations have been sedentary. *Curative.*—Investigations should be conducted for septic infection, especially from the teeth, the fauces, and the colon. Efforts should be directed towards the restoration of the patient's general bodily and mental health. To this end, fresh air and graduated exercises, especially in the form of games

to begin with, are enjoined. It is of great importance to secure an ample amount of sleep, and for this, as well as for excitability or irritability of the nervous system, bromides, at first in the usual dosage and continued in smaller dosage, are frequently of value. Digitalis is of no avail. Those cases in which there are indications of a slack vasomotor system are sometimes greatly relieved by wearing a belt to act as a general support for the abdomen.

FREDERICK W. PRICE.

CLINICAL ELECTRO-CARDIOGRAPHY

By means of the electro-cardiograph it is possible to obtain graphic records of the movements of both auricles and ventricles, to study the time-relations of their contractions, and to measure the function of conductivity, not only of the auriculo-ventricular junctional tissues, but also that below the division of the auriculo-ventricular bundle into two branches—that is, after its entrance into the ventricular muscle. In addition, it tells us the point of origin and path of conduction of the stimulus for contraction.

All the various forms of irregular action of the heart can be identified with certainty. The electro-cardiograph affords the most precise means of investigating the function of the myocardium. Disease of the myocardium, by interfering with the normal path of the wave of excitation, modifies the form of the ventricular complex. The instrument is often of great value in the diagnosis of coronary disease and infarction of the heart; it contributes the most certain sign of transposition of the heart; it gives evidence of left- or right-sided preponderance when either exists; it is sometimes of value in the diagnosis of chronic valvular disease and congenital morbus cordis; and during the administration of quinidine in the treatment of persistent auricular fibrillation and persistent auricular flutter, the changes in the cardiac rhythm induced by the drug may be followed, and the dosage controlled accordingly.

It has been known for a considerable time that changes in electric potential take place in muscle when it contracts, and, further, that a record of these changes may be obtained by connecting the muscle with a sensitive galvanometer by means of electrodes.

A. D. Waller, in 1887, employed a capillary electrometer to register the changes in electric potential in the human heart during contraction. He demonstrated that these changes were distributed through the body, and he used the moist skin surfaces of the arms and legs as leads, connecting them with a galvanometer.

Einthoven employed the string galvanometer to register the changes in electric potential in the human heart. He modified this instrument, the Einthoven string galvanometer being now generally employed in physiological and clinical investigations.¹ In the Einthoven galvanometer there is an exceedingly fine silvered glass fibre, which is suspended in a box and placed vertically between the poles of a powerful electro-magnet. When a current passes through this fibre, minute movements of the fibre

¹ The electro-cardiograph, supplied by the Cambridge Scientific Instrument Co. Ltd. is, in my opinion, the most satisfactory.

take place. The shadow of the oscillating fibre is magnified, and projected on to a photographic screen, and in this way a photograph of these movements is obtained. The sensitiveness of the fibre can be adjusted by altering the tension, the standard generally adopted being that of Einthoven, *i.e.* that when a difference of potential of one millivolt is passed through the fibre, this gives a deflection on the plate of 1 cm. in amplitude.

Recently some workers employ valve modification and a mirror galvanometer instead of the string galvanometer. Both varieties of electro-cardiographs are now made in reliable portable form, which can be taken to the bedside of the patient.

The common practice is to accept three leads and the following nomenclature, *i.e.* lead I, or the transverse, a lead from the right and left hands;

FIG. 60.—Electro-cardiogram of a normal subject. The first deflection, *P*, is due to the contraction of the auricles; the others are the result of the contraction of the ventricles, and are termed *Q*, *R*, *S*, and *T*. In normal subjects the amplitude of all the deflections is usually greatest in lead II, especially the deflection *R*.

lead II, or the axial, from the right hand and left foot; lead III, or the left lateral, from the left hand and left foot.

Oscillations may result from tremor of the somatic muscles, and may somewhat resemble those due to auricular fibrillation; the differential diagnosis will be discussed later.

The record of the changes in electric potential which take place in the heart during contraction is called an electro-cardiogram.

If a normal electro-cardiogram be studied, certain upward and downward deflections are seen in each cardiac cycle, the former being the more important (Fig. 60). These deflections may exhibit considerable variations in amplitude and form. Following Einthoven, the deflections are called *P*, *Q*, *R*, *S*, and *T*, in some instances *T* being followed by *U* during the early part of diastole. That portion of the electro-cardiogram from the beginning of *P* to the commencement of *Q* is called the auricular complex,

and that portion between the commencement of *Q* to the end of *T* is called the ventricular complex. The interval between *T* and the following *P* represents diastole.

FIG. 61.—Electro-cardiogram showing inversion of *T* in lead I. There is also left-sided preponderance.

FIG. 62.—Electro-cardiogram showing inversion of *T* in lead III.

The first deflection, *P*, is due to the contraction of the auricles. *Q*, *R*, *S* and *T* are due to the contraction of the ventricles. *P* is a small, blunt and rounded, upward deflection. Following *P* the string either remains at zero,

FIG. 63.—Electro-cardiogram showing inversion of *P* in lead III. There is also right-sided preponderance.

FIGS. 64, 65 and 66.—Electro-cardiograms from three different subjects, showing bifurcation of *R*.

or descends somewhat. *Q* and *S* are downward, steep deflections, usually of small amplitude. *Q* passes at once into *R*, which is an upward sharp spike, and of greater amplitude than any of the other deflections. *S* follows immediately upon *R*. During the interval between *S* and *T* the string remains

FIG. 67.—Electro-cardiogram showing bifurcation of *P*.

at zero. *T* is an upward, prominent, broad, blunt deflection. Inversion of *T* in lead I (Fig. 61) and in lead II may be regarded as pathological. Inversion of *T* in lead III (Fig. 62) may sometimes be pathological, but as it is not infrequently found in health its significance is uncertain in a single examination. It, therefore, follows that it is of essential importance to know whether the deflection was formerly upright. For the effect of digitalis, see p. 1006. If *P* (Fig. 63) be a downward deflection in lead I, II or III it is

FIGS. 68, 69 and 70.—Electro-cardiograms from three different subjects, showing bizarre types of *QRS* group of deflections.

abnormal. Bifurcation of *R* (Figs. 64, 65 and 66) and *S* is occasionally found in normal individuals, and of *P* (Fig. 67) more rarely. Bizarre types of the *Q*, *R*, *S* group of deflections are occasionally to be noted (Figs. 68, 69 and 70).

R and *T* are the most constant deflections, the former more especially so; *Q* and *S* are not infrequently absent; while the *U* deflection is of very uncommon occurrence.

In normal subjects the amplitude of all the deflections is usually greater in lead II, especially the deflection *R*, while the deflections in lead III are not infrequently of small amplitude.

The time-distance between the beginning of *P* and the commencement of *Q*, or between *P* and *R*, as the case may be, is an index of the *As-Vs* interval, that is, the interval separating the commencement of auricular and ventricular contraction, and is a measure of the function of conductivity of the auriculo-ventricular bundle above its division into two branches; it is called the *P-Q* or *P-R* interval. The rule is to employ the *P-R* interval, on account of the frequent absence of the *Q* deflection. In normally acting hearts this interval does not measure more than 0.18 second (Fig. 60). If it exceeds this (Fig. 85), we may conclude that there is delay in the conduction of the stimulus from auricle to ventricle; this means that the function of conductivity is depressed, and that probably there is some affection of the auriculo-ventricular bundle. The *P-R* interval is a more reliable indication of the rate of conduction of the stimulus for contraction than the *a-c* interval

Fig. 71.—Electro-cardiogram in which *P* and *T* coincide and superimpose.

in a polygraphic tracing, because the presphygmic interval and the period between the opening of the aortic valves and the carotid pulse are not included. The period of time occupied by the ventricular complex is approximately that of the ventricular systole. The initial group of ventricular deflections (*Q*, *R*, *S*) corresponds to the initial events of ventricular systole—in other words, to the spread of the wave of excitation in the ventricular muscle. The period of time occupied by this group is of great importance, being a measure of the time during which the various parts of the ventricular muscle are passing into activity. It is normally not more than one-tenth second. If it is increased, it indicates a delay in the conduction of the wave of excitation through the ventricular muscle. The period of time between the *S* and *T* corresponds with the time during which the mass of the ventricular muscle is in contraction. The *Q-T*, or *R-T*, interval occupies about 0.32 second. When the cardiac rate is unusually frequent the duration of the diastolic interval is shortened, so that the deflection *T* approaches more and more to the following *P*, and *P* and *T* may even coincide and superimpose (Fig. 71).

The form of electro-cardiographic curves depends upon the point of origin and paths of conduction of the stimulus for contraction; any departure from the normal in respect of either of these will, therefore, result in a

corresponding alteration in the form of the electro-cardiogram. A normal *P* signifies that the stimulus for contraction arises in the remains of the sinus venosus at the orifices of the great veins, and that from this point the stimulus spreads over the whole of the auricles along the normal paths. When *P* is abnormal, as, for instance, inverted, it is believed that the stimulus for contraction arises at some site other than the sino-auricular node, or that the paths of conduction are abnormal. Similarly, a normal ventricular complex signifies that the ventricles have contracted in response to a stimulus which has arisen above the level of the division of the auriculo-ventricular bundle into its two main branches, and that from this point the stimulus proceeds along the normal paths; and an abnormal ventricular complex signifies either that the stimulus for contraction has arisen at some point below

FIG. 72.—Electro-cardiogram showing predominant hypertrophy of the left ventricle.

the level of the division of the auriculo-ventricular bundle, or that, when supra-ventricular in origin, the paths of conduction are abnormal.

Electro-cardiograms of a number of healthy persons all present different features, but the curve in each case will present individual characteristics which are constant. The form of electro-cardiogram is modified by age, and by displacement of the heart—from whatever cause. Diminution in the amplitude of *T* occurs with advancing age.

CARDIAC HYPERTROPHY.—It has been previously pointed out that in cardiac hypertrophy, while both ventricles are more often affected than one alone, one ventricle is frequently involved to a greater degree than the other. This predominant hypertrophy or preponderance of either ventricle is revealed by the electro-cardiograph. If in cardiac hypertrophy an electro-cardiogram does not indicate either right- or left-sided preponderance, we may assume that the hypertrophy involves both ventricles approximately equally.

In left-sided preponderance, in lead I, *R* is large and may be very large

and *S* is small or absent; in lead III, *R* is small or absent, and *S* is deep and may be very deep, and *Q* is most pronounced in lead I (Figs. 61 and 72). The deflections of greatest amplitude in leads I and III, therefore, point away from each other.

In right-sided preponderance, in lead I, *R* is small or absent, and *S* is deep and may be very deep; in lead III, *R* is large and may be very large, and *S* is small or absent; and *Q* is most pronounced in lead III (Figs. 63 and 73). The deflections of greatest amplitude in leads I and III, therefore, point towards each other.

In marked left-sided preponderance, such as in aortic valvular disease or in hypertension, there is often inversion of *T* in lead I; and in marked right-sided preponderance there is frequently inversion of *T* in lead III. Barnes and Whitton have suggested that these changes in the *T* deflections

FIG. 73.—Electro-cardiogram showing predominant hypertrophy of the right ventricle.

result from mechanical strain on one ventricle rather than actual disease of the myocardium, other than hypertrophy.

In extreme preponderance of either ventricle, the period of time occupied by the *Q*, *R*, *S* group of deflections may be increased, exceeding one-tenth of a second.

In the diagnosis of preponderance of either ventricle it is necessary to exclude displacement of the heart, for the following reason. The electrical axis of the organ is influenced by the anatomical axis, so that displacement may give rise to electro-cardiographic curves of right- or left-sided preponderance. Thus, a horizontal position of the heart with a high diaphragm tends to produce a curve of left ventricular preponderance; while a vertical position of the heart with a low diaphragm, as seen in asthenic subjects, tends to produce that of right ventricular preponderance.

It is also necessary to distinguish between predominant hypertrophy of

the left or right ventricle and a lesion of the left or right main branch of the auriculo-ventricular bundle (new nomenclature) respectively. This is referred to on p. 997.

FIGS. 74 and 75.—Electro-cardiograms from two different subjects, showing increased amplitude of the deflection *P*.

It is said that the amplitude of *P* is increased (Figs. 74 and 75), or even doubled, in hypertrophy of the auricles. Some writers, however, state that this is occasionally to be met with in normal hearts.

FIGS. 76 and 77.—Electro-cardiograms from two different cases of mitral stenosis. The deflection *P* is increased in amplitude, and is also broad, has a flat top, and is bifurcate.

CHRONIC VALVULAR DISEASE.—In many cases of aortic incompetence the ventricular complexes are the same as those of predominant hypertrophy of the left ventricle. In mitral stenosis the amplitude of the deflection *P* is often markedly increased, and not infrequently it is also broad, has a flat top, and is bifurcate (Figs. 76 and 77). These features, when present, are of diagnostic value. While a marked increase in the amplitude of the de-

deflection *P* is especially found in mitral stenosis in which there is hypertrophy of the auricles, in my opinion it is not justifiable to diagnose the lesion from this alone. In many cases of mitral stenosis the ventricular complexes are the same as those of predominant hypertrophy of the right ventricle. When auricular fibrillation supervenes in mitral stenosis, the curves will present features characteristic of that condition. In many cases of aortic incompetence, the ventricular complexes are the same as those of predominant hypertrophy of the left ventricle.

CONGENITAL HEART DISEASE.—It is said that an increase in the amplitude of the deflections is often found in congenital heart disease.

FIG. 78.—Electro-cardiogram from a case of transposition of the heart. All the deflections in lead I are inverted.

TRANSPOSITION OF THE HEART.—In this condition all the deflections of a curve from lead I are inverted (Fig. 78). It is believed that this form of electro-cardiogram is found in no other condition.

SINUS IRREGULARITY.—The electro-cardiogram of this rhythm may readily be identified (Figs. 79–81). As the stimulus for contraction takes its origin at the physiological site, and from this point pursues a normal course, the auricular and ventricular complexes are of normal form, and the ventricular complexes follow the *P* deflections after a normal interval. As, however, there is a variation in the length of the diastolic intervals, variations are found in the length of the interval between *T* and *P*.

EXTRA-SYSTOLES.—Extra-systoles may be readily recognised by means of the electro-cardiograph, and usually their site of origin.

In the ventricular variety (Fig. 82) the ventricular complex occurs earlier than the anticipated time. As the point of origin of the stimulus for contraction is below the division of the auriculo-ventricular bundle into its two branches, it is abnormal in form; it is of larger amplitude and is diphasic.

FIGS. 79, 80 and 81.—Electro-cardiograms from three different subjects, showing sinus irregularity. The auricular and ventricular deflections are of normal form, but there are variations in the length of the interval between *T* and *P*.

FIG. 82.—Electro-cardiogram showing ventricular extra-systoles, marked *Ex.S.* The corresponding *P* deflections are embedded in the diphasic variations. There is also inversion of *T* in lead I, and left-sided preponderance.

There are two main varieties of ventricular extra-systoles, and it is usually possible to differentiate them by means of the electro-cardiograph. In one, the ventricular complex consists of an upward, tall and pointed deflection, and then of a downward and broader deflection, in lead I; and of a downward, deep and pointed deflection, and then of an upward and broader deflection, in lead III. In the other variety, the ventricular complex consists of a downward, deep and pointed deflection, and then of an upward and broader deflection, in lead I; and of an upward, tall and pointed deflection, and then of a downward and broader deflection, in lead III. It is probable that the first variety has its origin in the left ventricle or apical portion of the heart, and the second in the right ventricle or basal portion of the heart. As in the case of bundle-branch block, however, the question is at present sub judice. The direction of the deflections in lead II is usually the same as in lead III, but the reverse may be the case.

In the ventricular variety of extra-systoles, the auricle maintains its

FIG. 83. Electro-cardiogram showing auricular extra-systoles, marked *Ex.S.* The premature *P* deflections are of normal form in lead I, and of abnormal form—being inverted—in lead II. The premature ventricular complexes are of abnormal form. The third extra-systole in lead I is blocked.

usual rhythm, and contracts as the result of the normal stimulus from the sinus. It follows, therefore, that the corresponding *P* deflection appears at the anticipated time and is normal in form. But it is usually embedded in the ventricular complex, although it may be detected in this part of the electro-cardiographic curve in some cases, and occasionally is nearly separate.

If the ventricular extra-systole take place after the normal auricular contraction, and the wave of contraction from the auricle have reached the ventricle and met that of the premature ventricular contraction in the ventricular wall, the ventricular complex of the premature contraction of the ventricle will present both normal and abnormal features.

The site of origin of an extra-systole may occasionally be at one time the basal or right portion of the ventricle, and at another the apical or left portion, in the same subject.

The departure from the normal form of electro-cardiogram is not nearly so pronounced in auricular as in ventricular extra-systole. In this variety (Fig. 83), the *P* deflection takes place before the anticipated time. As the point of origin of the stimulus for contraction is at a site other than the sino-auricular node, the *P* deflection is usually abnormal in form, often being inverted

(lead II). Sometimes, however, the premature *P* deflection is of normal form (lead I). The *P* deflection is usually followed by a premature ventricular complex. This is usually of normal form, since the stimulus for contraction is supra-ventricular in origin and thence travels along the usual paths. Sometimes, however, the premature ventricular complex is of abnormal form (Fig. 83), due to the stimulus for contraction from the premature contraction of the auricle not reaching the various portions of the ventricular muscle in the normal manner. It may be even diagnosed as arising below the division of the auriculo-ventricular bundle into two branches. Abnormal ventricular complexes are almost always found only when there is diminished conduction along the auriculo-ventricular junctional tissues; and in some cases the stimulus for contraction does not reach the ventricle at all, in which case the premature contraction of the auricle is not followed by a premature contraction of the ventricle—"blocked auricular extra-systole" (third extra-systole in lead I of Fig. 83). In auricular extra-systole, the premature contraction

FIG. 84.—Electro-cardiogram showing auriculo-ventricular extra-systoles, marked *Ex.S.* In that of lead I the premature *P* deflection occurs before that of the ventricular complex, while that in lead II is embedded in the ventricular complex.

of the auricle may take place so early as to coincide with the ventricular contraction of the preceding cycle, in which case *P* and *T* superimpose.

In the auriculo-ventricular variety (Fig. 84), there is prematurity of the *P* deflection, and also of the ventricular complex. The ventricular complex is of normal form, as its stimulus for contraction is supra-ventricular in origin and thence travels along the normal paths. In cases in which the premature contraction of the chambers is absolutely synchronous, the *P* deflection is embedded in the ventricular complex (in lead II). When, on the other hand, the auricular contraction occurs before that of the ventricle, the *P* deflection is of abnormal form, often being inverted, and the *P*-*R* interval is diminished (in lead I).

Occasionally the beat immediately following an extra-systole arises from the same site as that of the premature contraction.

SINO-AURICULAR BLOCK.—In this condition there is an absence of both the auricular and ventricular complexes during the abnormally long pause.

AURICULO-VENTRICULAR BLOCK.—In the first degree of depressed conductivity (leads I and III of Fig. 85) there is merely an increase of the *P*-*R* interval, it exceeding 0.18 second. In the second degree, the *P* deflections

are found at regular intervals and are normal in form, but more frequent than the ventricular complexes—even twice (lead II of Fig. 85), three times or more, according to the degree of block ; in other words, sometimes the *P*

FIG. 85.—Electro-cardiogram showing partial heart-block. In each lead there is an increase of the *P-R* interval, and in lead II there is also continuous 2 : 1 rhythm, every other stimulus from the auricle failing to reach the ventricle. There is also inversion of *T* in lead III and left-sided preponderance.

FIG. 86.— Electro-cardiogram of leads I and II, showing complete heart-block, or disassociation of the auriculo-ventricular rhythm, the auricles and ventricles beating independently of each other.

deflections are not followed by ventricular complexes. But, unlike complete heart-block, on each occasion the ventricular complex is preceded by a *P* deflection. In complete heart-block (Fig. 86), the *P* deflections are found at regular intervals and are normal in form, and besides being more frequent than the ventricular complexes, the time-relation between the *P* deflections

and the ventricular complexes is a constantly varying one—the *P* deflection at one time preceding, at another following, and sometimes again coinciding with the ventricular complexes. The ventricular complexes are of normal

FIG. 87.—Electro-cardiogram showing a lesion of the left main branch of the auriculo-ventricular bundle (new nomenclature).

FIG. 88.—Electro-cardiogram showing a lesion of right main branch of the auriculo-ventricular bundle (new nomenclature). There is also auricular fibrillation.

form, as the point of origin of the stimulus for contraction is above the division of the auriculo-ventricular bundle into its two branches.

BUNDLE-BRANCH BLOCK.—A lesion of either of the two main branches

of the auriculo-ventricular bundle may be recognised by means of the electrocardiograph. When the right branch is involved, the wave of excitation from the auricle travels to both ventricles along the left branch, the left ventricle thus being excited before the right. When the left branch is involved, the wave of excitation travels along the right branch only, the right ventricle being excited first. Each ventricular complex is preceded by a normal auricular deflection, *P*, but the form of the ventricular complexes is abnormal and characteristic. The ventricular complexes are of increased amplitude and diphasic. The initial deflections, *Q*, *R*, *S*, are wider than normal, exceeding one-tenth of a second in duration, and usually notched or splintered. The terminal deflection, *T'*, points in the opposite direction to the main initial deflection in leads I and III. In lead II, *Q*, *R*, *S* is usually of less amplitude and often diphasic; *T'* may point in either direction. In the diphasic ventricular complexes of leads I and III there is usually no isoelectric period between *Q*, *R*, *S*, and *T*.

It has hitherto been supposed that in right bundle-branch block the main initial deflection is directed upwards in lead I, and downwards in lead III, as in left ventricular preponderance; and that in left bundle-branch block the main initial deflection is directed downwards in lead I and upwards in lead III, as in right ventricular preponderance. This terminology of bundle-branch block curves was based largely on experiments on animals. Pathological investigations in cases of bundle-branch block in man have sometimes lent support to these experimental observations, but not constantly. Recently, Oppenheimer, Wilson and other workers in America have adduced evidence, based partly on direct observations on the exposed human heart, which suggests that curves hitherto designated right bundle-branch block indicate left bundle-branch block, and vice versa. The whole question is at present sub judice, and is of academic rather than of practical importance. At present, two types of curves indicative of block in a main division of the bundle may be recognised: (1) The common type (hitherto termed right bundle-branch block), in which there is a large *R'* in lead I and a large *S* in lead III, *T'* pointing downwards in lead I and upwards in lead III. (2) The rare type (hitherto termed left bundle-branch block) in which there is a large *S'* in lead I, and a large *R* in lead III, *T'* pointing upwards in lead I and downwards in lead III.

It is necessary to distinguish between preponderance of the left or right ventricle and a lesion of the left or right main branch of the auriculo-ventricular bundle (new nomenclature) respectively. The distinguishing features are that in bundle-branch block, the initial deflections, *Q*, *R*, *S*, are wider than normal, and are usually notched or splintered, and *T'* points in the opposite direction to the main initial deflection in leads I and III.

PARTIAL BUNDLE-BRANCH BLOCK.—In this condition either of the two main branches of the auriculo-ventricular bundle may be affected in one of the two following ways: (1) The wave of excitation along the affected branch is merely delayed. (2) More rarely, some only of the waves of excitation along the affected branch are blocked, and travel to both ventricles along the other branch. Cases of 2:1 partial bundle-branch block have been recorded.

In the first variety of partial bundle-branch block the ventricular com-

plexes are transitional in form between those of complete bundle-branch block and those of the normal supra-ventricular type. In the second variety the electro-cardiogram shows some ventricular complexes of complete bundle-branch block form and others of the normal supra-ventricular type.

FIGS. 89-93. -- Electro-cardiograms from cases of auricular fibrillation.

INTRA-VENTRICULAR (ARBORISATION) BLOCK.—In this condition there is diminished conduction in the Purkinje fibres, and it is believed by some that it may be recognised by means of the electro-cardiograph. The initial part of the ventricular complex (*Q*, *R*, *S*) is wider than normal, usually exhibits notching or splintering, and the curve is of low voltage.

ALTERNATION OF THE HEART.—This may be sometimes recognised by means of the electro-cardiograph, by an alternation in the amplitude of the deflections due to the contraction of the ventricle (Fig. 97). Both the *R* and *T* waves may be affected, or one more than the other. It should be noted that alternation of the heart is sometimes shown in a sphygmogram without any corresponding evidence in an electro-cardiogram, while rarely the opposite holds good. It should be further noted that the alternation in a sphygmogram and electro-cardiogram does not always correspond; *i.e.* the smaller ventricular deflections correspond with the larger pulse-wave.

AURICULAR FIBRILLATION.—In auricular fibrillation the electro-cardiogram is characteristic (Figs. 89–93). Apart from the very rare cases of complete auriculo-ventricular block, when the rhythm is regular, the rhythm of the ventricular complexes is *completely* irregular; the *R* deflections occur at irregularly irregular intervals; the amplitude of the *R* deflections varies from cycle to cycle; and there is often no relationship between the length of a pause and the amplitude of the *R* deflection which follows it—*i.e.* a short pause may be followed by an *R* deflection of large amplitude and a long pause by one of small amplitude. When the ventricular rate is slow or very rapid, the irregularity may be only slight. When the ventricle contracts only in response to stimuli received from the auricle through the normal channel, all the ventricular complexes are of normal form. Such, however, is not the case when there are superadded ventricular extra-systoles, or when there is also a lesion of either main branch of the auriculo-ventricular bundle (Fig. 88).

There is an absence of *P* deflections; these cannot be present because the auricle does not contract. There are, on the other hand, oscillations during diastole caused by the fibrillating auricle, occurring at the rate of about 450 per minute, and irregular in time and form. These are most evident in cases of slow cardiac action, whereas if the action be frequent it is often difficult to detect them. Their size varies, being sometimes very minute and sometimes of considerable size. They may coincide with the *T* deflections, in which case the outline of the latter is altered.

These oscillations should be distinguished from those which occur as a result of tremor of the somatic muscles. These are of frequent occurrence in the subjects of Graves' disease, and may be of considerable size. Oscillations due to auricular fibrillation may be distinguished from those resulting from tremor of the somatic muscles by the fact that in the latter case they are of more frequent occurrence—about 50 per second—and occur at regular intervals, the deflection *P* or some indication of it may be noted, and the ventricular complexes do not occur at irregularly irregular intervals.

It is further necessary to distinguish electro-cardiograms of auricular fibrillation from those of auricular flutter. This will be referred to later.

AURICULAR FLUTTER.—In this condition it is of especial importance to analyse the three leads (Figs. 94–96). The *P* deflections may range from 180 to 380, perhaps being usually between 280 and 300 per minute. In all leads they occur at regular intervals, and are of abnormal form, often being inverted, and in each lead of any given case they are almost invariably of constant form. In lead I their amplitude is comparatively small, while in leads II and III their amplitude is greater. Almost invariably there are two or more *P* deflections to each ventricular complex. The latter usually occur at regular intervals, and are of normal form, being of supra-ventri-

1000 DISEASES OF THE CIRCULATORY SYSTEM

cular origin. The ventricular complexes are superimposed, modifying the outline of some, or very rarely all, of the *P* deflections. In some instances *T* may be detected.

As has just been noted, it is necessary to distinguish the electro-cardio-

FIG. 94.—Electro-cardiogram from a case of auricular flutter, with 2 : 1 heart-block. The rate of the auricle is between 320 and 330 per minute.

FIG. 95.—Electro-cardiogram from a case of auricular flutter, with 4 : 1 heart-block.

grams of auricular flutter from those of auricular fibrillation. In the case of the latter, the *R* deflections occur at irregularly irregular intervals; the amplitude of the *R* deflections varies from cycle to cycle; and there is often

FIG. 96. —Electro-cardiogram from a case of auricular flutter. The auriculo-ventricular ratio is sometimes 2:1, at others 3:1, and at others again 4:1. The response of the ventricle to auricular contraction being at irregular intervals, there is irregularity of the ventricular rhythm.

FIG. 97. —Electro-cardiogram from a case of paroxysmal tachycardia. The point of origin of the new rhythm is situated in the auricle. The *P* deflection is inverted and coincides with the ventricular contraction of the preceding cardiac cycle. It might be regarded as auricular flutter, in which the ventricle responds to each auricular contraction. The rate is between 190 and 200 per minute. There is alternation in the amplitude of the *R* deflections.

1002 DISEASES OF THE CIRCULATORY SYSTEM

no relation between the length of a pause and the amplitude of the deflection *R* which follows it, *i.e.* a short pause may be followed by an *R* deflection of large amplitude, and a long pause by one of small amplitude. In the case of auricular flutter, it will be found that these features are not present, even though the ventricular rhythm is markedly irregular. Further, the deflections due to auricular systole in cases of auricular flutter may be distinguished from the oscillations found in auricular fibrillation. In the case of the former, they are less frequent, rhythmic, and almost invariably of constant form; whereas in the latter they are more numerous, irregular in rhythm, and inconstant in form.

NODAL RHYTHM.—In this condition the ventricular complex is of normal form, as it is supra-ventricular in origin. In cases in which the premature

FIG. 98.—Electro-cardiogram showing short paroxysms of ventricular extra-systoles. There is also inversion of *T* in lead I and left-sided preponderance.

contraction of the chambers is absolutely synchronous, the *P* and *R* superimpose. When, on the other hand, the auricular contraction occurs before that of the ventricle, the *P* deflection is of abnormal form, often being inverted, and the *P-R* interval is diminished.

PAROXYSMAL TACHYCARDIA.—As might be inferred from what has been stated on page 882, electro-cardiograms present different features, according to the point of origin and paths of conduction of the stimulus for contraction; for example, they may indicate auricular flutter, paroxysms of auricular systoles, auricular fibrillation, nodal rhythm, or paroxysms of ventricular extra-systoles (Fig. 98).

ANGINA PECTORIS.—Left-sided preponderance is usual. In a proportion of cases the ventricular complexes are abnormal. Most varieties of these abnormalities may be met with, including flattening or inversion of *T* in lead I, or II, or both; increased duration, and notching of the *Q, R, S* group of deflections; bundle-branch block; and a large *Q* deflection in lead III

(see below). There may be extra-systoles and some degree of heart-block. Other abnormalities of rhythm are exceptional. The changes in the ventricular complexes may be of considerable value in doubtful cases. Negative findings, on the other hand, are of no importance.

Transient modifications of the electro-cardiograms similar to those of coronary occlusion with acute infarction have been observed in some cases of angina pectoris during the attacks. Such are of great diagnostic value.

CORONARY OCCLUSION WITH ACUTE INFARCTION OF THE HEART.—Electro-cardiograms of this disease are usually characteristic and of great diagnostic value. They are as follows:

There is usually an alteration in the *R-T* (or the *S-T*) interval. This

FIG. 99.—Electro-cardiogram from a case of infarction of the heart. Taken four days after the onset of symptoms. The *R-T* interval in lead I is in the form of a plateau-shaped elevation, and the *S-T* interval in lead III is in the form of a plateau-shaped depression, as indicated by arrows. After Parkinson and Bedford (*The Lancet*).

portion of the curve commences from the *R* or *S* deflection, either above or below the zero level, and afterwards proceeds in a more or less horizontal direction until the *T* deflection is reached, resulting either in a plateau-shaped elevation or in a plateau-shaped depression, respectively. This alteration is usually most noticeable in leads I and III, in which event the corresponding portions of the curves in these leads point away from each other—thus, when there is an *R-T* elevation in lead I there is an *S-T* depression in lead III (Fig. 99), and vice versa. Sometimes, however, it is best observed in leads I and II, or in leads II and III and in either case the corresponding portions of the curves point in the same direction; or the alteration may be present in one lead only. The foregoing features are perhaps pathognomonic of the condition.

From a few days to a few weeks later the R - T (or the S - T) portion of the curve returns to the zero level. Usually characteristic changes in the T deflections in one or more leads, generally the latter, are also to be noted (Figs. 100 and 101). If more than one lead is implicated, perhaps most frequently leads III and II, and next most commonly leads I and II are concerned; while if only one lead, either lead III or I. The T deflections become inverted, their form is usually that of a sharp spike, and their amplitude is often large. The T deflections point in the opposite direction to that of the previous deviation of the R - T or the S - T intervals respectively. The R - T (or the S - T) interval preceding an inverted T deflection often exhibits

FIG. 100.—Electro-cardiogram from a case of infarction of the heart. Taken two and a half weeks after the onset of symptoms. The T deflections in all leads are spiked and of large amplitude, and those in leads II and III are also inverted. After Parkinson and Bedford (*The Lancet*).

FIG. 101 Electro-cardiograms from a case of infarction of the heart. Taken three weeks after the onset of symptoms. The T deflections in lead I are inverted; their form is that of a sharp spike, and their amplitude is rather large. The T deflections in lead II are inverted. After Parkinson and Bedford (*The Lancet*).

upward convexity. These features are not so characteristic as are those of the first stage, but, taken together with the clinical features, they afford strong corroborative evidence of the disease.

In both the foregoing stages, the initial group of ventricular deflections (Q , R , S) usually exhibits diminished amplitude, the period of time occupied by the complex is often increased, and the latter is usually associated with notching or splintering.

Some changes in the T deflections towards the normal generally supervene within a few weeks or months, and ultimately the T deflections in all leads may become normal, but sometimes those in one lead remain inverted and sharply spiked, and even these changes are very suspicious.

A large *Q* deflection in lead III (see Fig. 102) is often a noticeable feature of electro-cardiograms of coronary occlusion. This, however, is sometimes

FIG. 102. - Electro-cardiogram from a case of coronary occlusion, showing a large *Q* in leads II and III. There is also the characteristic inversion of *T* in the same leads.

FIG. 103. Electro-cardiogram from a case of auricular fibrillation fully under the influence of digitalis.

also met with in atheroma of the coronary arteries apart from occlusion, being a suggestive sign of this disease.

The foregoing changes in the electro-cardiograms of coronary occlusion

with acute infarction of the heart are not constant. But they are frequent, and when they do occur are of great diagnostic value. It is necessary to point out that it is the successive changes in the curves which are especially important. For this reason, serial records taken over a period of time are of much greater value than a single one, for in cases in which the latter does not reveal the characteristic changes, later curves may do so. It is unusual to find an absence of these changes during the whole of the first two weeks after the onset of symptoms, though transient changes may have disappeared in later electro-cardiograms.

In conclusion, deviation in the *R-T* (or *S-T*) interval has also been recorded in rheumatic carditis, pericardial effusion, pneumonia and uræmia. The clinical features of these conditions, however, do not resemble those of coronary occlusion.

It has been pointed out that transient changes in the electro-cardiograms similar to those of coronary occlusion have been observed during attacks of angina pectoris.

THE EFFECT OF DIGITALIS.—Electro-cardiograms of patients fully under the influence of digitalis may show depression of the *R-T* interval and of the *T* deflection itself in all leads (see Fig. 103). This should be distinguished from the *R-T* deviation due to coronary occlusion. In the former the corresponding portions of the curves always point in the same direction; while in the latter usually they point away from each other in leads 1 and III.

FREDERICK W. PRICE.

DISEASES OF THE BLOOD VESSELS

Disease of the arteries should be classified from the pathological standpoint. Much confusion has arisen from the use of the term *arterio-sclerosis*, which means arterial hardening. This term has been applied to at least four distinct pathological arterial conditions :

(a) It has been applied to arteries which have become hardened as the result of inflammation. Chronic inflammation of arteries, or chronic arteritis, is usually the result of syphilis, but may be caused by other infections.

(b) In the degeneration of the intima of the arteries, which is known as atheroma, calcification may take place and the artery become hardened. Marchand has given the name athero-sclerosis to this form of arterial hardening.

(c) Degeneration of the middle coat of the artery is also termed arterio-sclerosis. This form of hardening is especially marked in those arteries which are affected by Mönckeberg's degeneration. The degeneration is accompanied by a deposition of lime-salt in the middle coat. The lime-salt is deposited, more or less symmetrically, in rings round the artery.

(d) The term arterio-sclerosis has also been applied to hypertrophied arteries. Here the artery is increased in size, owing to an increase in its muscular elements, which are found mainly in the middle coat, and, to a less degree, in both layers of the intima. Muscular hypertrophy is the essential change in high arterial pressure.

It is therefore clear that the term arterio-sclerosis should not be used in

describing arterial disease. The classification of arterial disease by Professor Turnbull (*Quart. Journal Med.*, 1915) is here adopted :

- (1) Arterial inflammation.
- (2) Arterial degeneration : (a) degeneration of the intima ; and (b) degeneration of the media.
- (3) Arterial hypertrophy.
- (4) Arterial infiltration, of which the chief example is amyloid infiltration.

ARTERIAL INFLAMMATION

The arteries may be infected from their intima, either by micro-organisms settling on the surface, or by the arrest of an infective embolus within the lumen. They may also be infected by micro-organisms reaching the media or adventitia through the vasa vasorum, or by direct inward spread of inflammation from the surrounding tissues.

ACUTE ARTERITIS

Acute arteritis was formerly described as a common event in many diseases, the old authorities mistaking staining of the intima for inflammation. Acute inflammation of the arteries is, however, a rare disease, and is usually met with as a complication in the acute infections. The intima of the aorta may be infected in cases of septicæmia and pyæmia. This occurs most commonly in cases of progressive septic endocarditis, and the organisms usually found are streptococci. Vegetations may be seen upon the intima, and the inflammation rapidly involves the subjacent coats. Occasionally the aorta may be infected in a septicæmia or pyæmia, through embolism of the vasa vasorum, or the ascending aorta may be infected by spread through the vessel wall from a pericarditis. The wall of the aorta may rupture, or an aneurysm be formed. Acute multiple arteritis is most frequently seen as a sequel of typhoid fever, but cases have been observed after small-pox, scarlet fever, influenza and pneumonia. In many cases the organisms of the disease have been found in the vessel wall.

Symptoms.—The symptoms depend upon the vessels affected. In the case of the femoral artery, there may be severe pain in the course of the vessel with sometimes redness and swelling in the part affected. The pulse below is obliterated. The limb becomes pale and cold, and then livid. Gangrene may or may not follow ; it depends upon the rapidity with which the vessel is blocked. In some cases where the onset is severe, and the symptoms suggest that gangrene will follow, the circulation improves and colour returns to the limb. In other cases, several of the arteries may be infected at the same time, with high fever and symptoms of an acute infection.

Prognosis and Treatment.—In acute arteritis treatment is of little avail, the infection always being a very severe one. Every effort should, however, be made to avoid infectious gangrene, and in some cases a surprising return of circulation may be observed.

CHRONIC ARTERITIS

Ætiology.—Acquired syphilis is by far the most common cause of chronic arteritis, which may, however, follow congenital syphilis. Tuberculous

endarteritis is not uncommon in the small pulmonary arteries and in the arteries of the brain in tubercular meningitis. Endarteritis obliterans may also be caused by infection with pyogenic organisms of a subacute or chronic type. Moreover, changes in the adventitia of the small arteries are also found in polio-encephalo-myelitis and in encephalitis lethargica.

Pathology.—Chronic arteritis is a focal affection, and is found in muscular and elastic arteries of all calibres. It is common in the aorta and large elastic arteries, and it also frequently attacks the small arteries. The large muscular arteries, however, are but rarely affected by syphilis. Chronic inflammation of the arteries has been divided into—(1) Endarteritis, where the intima is affected; (2) mesarteritis; and (3) periarteritis, where the external coat is involved. In the great majority of cases of inflammation of the smaller arteries all coats are involved. The muscular and elastic fibres tend to be destroyed, and this may result in direct rupture. The changes in the intima are very conspicuous. Its layers become very much thickened by inflammatory infiltration and proliferation. In the early stages round cells are seen, and later spindle-shaped fibroblasts appear, definite granulation being thus formed, while in cases of syphilis plasma cells and eosinophil leucocytes are often present. The result of this great thickening in such small arteries is markedly to narrow the vessel, and the condition is often termed endarteritis obliterans. The lumen of the vessel may finally become completely blocked, leading in the brain to cerebral softening, and in other tissues to fibrosis. The adventitia is also greatly thickened in chronic syphilitic arteritis and consists of inflamed tissue infiltrated by lymphocytes, plasma cells and occasional eosinophil leucocytes.

Syphilis of the aorta or syphilitic mesaortitis is a focal inflammation, but it may implicate almost the whole length of the aorta. The inflammation extends from the adventitia. The vasa vasorum proliferate, and in most cases pass into the intima. About these vessels is a zone of granulation tissue. Usually this consists only of plasma cells, lymphocytes, eosinophil leucocytes and fibroblasts, but occasionally there are gummata with giant cells. Endarteritis of the vasa vasorum is found only in the more intense reactions. The elastic fibres of the media are completely destroyed in the areas of granulation tissue; occasionally the media is necrosed between areas of granulation tissue. The *Sp. pallida* has been demonstrated in the lesions. The intima of the aorta is usually thickened over the areas of inflammation, and this thickening has been in the past confused with the degeneration of the intima which we know as atheroma. The inflammatory thickening of the intima due to syphilis can, in its earlier stages, be distinguished by the naked eye from atheromatous thickenings by its greater latitude and prominence, its pearly colour, its rubber-like consistency, crenated outline, pitted surface and freedom from fatty degeneration. The weakening of the vessel wall on account of the replacement of the middle coat frequently results in dilatations, varying in size from minute stellate patches to large aneurysms. The scarring and pitting are due to fibrous tissue replacing the inflamed media and are characteristic of the condition. It should be added that in the later stages atheroma usually occurs in the thickened intima over the areas of inflammation; also that syphilitic mesaortitis and primary atheroma may co-exist, especially in later life.

The coronary arteries of the heart are often found affected in these cases.

Owing to the mesoarteritis of the ascending aorta, the orifices of the coronary arteries become narrowed or blocked. This may cause extensive necrosis or fibrous patches in the myocardium. The heart is, therefore, not uncommonly enlarged. In addition, frequently we find that the aortic ring has expanded, or the aortic valves have become involved by the syphilitic inflammation, so that aortic regurgitation is a common sequel.

The *arteries of the brain* are frequently involved by syphilis, which causes endarteritis obliterans, and consequent cerebral softening. This change is also present in syphilitic meningitis, where the syphilitic inflammatory reaction is more intense. The kidneys are but rarely affected, though occasionally gummata are found. The eyes are not infrequently attacked, and a condition of syphilitic choroido-retinitis may be seen on ophthalmoscopic examination. In other organs, such as the liver and testicle, gummatous necrosis, followed by fibrous changes, is found. In rarer instances the trachea and lungs are affected.

Symptoms. The symptoms that result from syphilitic vascular disease depend upon the organ affected.

In the aorta, the symptoms of aneurysm are a common result from syphilis. Aortic regurgitation, with its usual effect on the heart, is also common. The symptoms of necrosis or fibrosis of the myocardium are severe anginal pains, often resulting in sudden death. Occasionally the heart muscle may give way and the heart dilate, with the usual signs of chronic cardiac failure. If the brain is affected by arterial thrombosis, the symptoms depend upon the area affected; hemiplegia, aphasia and hemianopia may all result. Albuminuria is quite uncommon in syphilitic vascular disease. Iritis may be present, but the usual condition found in the fundi is choroiditis. White patches surrounded by pigmented areas give a striking appearance to the fundus oculi in these cases. The optic disc is often white and atrophied. In syphilitic meningitis, oedema of the optic papilla is often present. The radial artery is practically always normal to the touch in cases of syphilitic vascular disease.

Course. The course of syphilitic arterial disease is extraordinarily variable. The symptoms are generally present in the acute secondary stage, from 2 to 5 years from the date of infection, but the vascular disease may exist with exacerbations all through life.

Prognosis.—The prognosis in syphilitic vascular disease is on the whole good, if the condition be taken early enough and treated properly. It has to be remembered, however, that vascular syphilis is often complicated by parenchymatous syphilis, where the spirochaetes are not only found in the walls of the vessels, but also in the cerebro-spinal tissues themselves, and this complication certainly increases the gravity of the condition.

Treatment.—Prophylaxis is of the greatest importance in syphilitic vascular disease. With regard to treatment, in the acute stages of syphilitic vascular disease it cannot be too strongly urged that mercury is the best drug to use. Mercurial inunctions or soluble intramuscular mercurial injections should be given for 2 or 3 weeks before any intravenous injections are prescribed. Moreover, iodides should be given by the mouth, to absorb as far as possible the inflammatory products in the intima of the vessels and to decrease the viscosity of the blood. There is no doubt that the indiscriminate use of salvarsan and neo-salvarsan in the acute stages of

syphilitic vascular disease has been followed by most disastrous results. The administration of these strong anti-syphilitic remedies causes further swelling of the intima and further blocking and thrombosis of the small vessels. After mercury and iodides have been given for 2 or 3 weeks, neosalvarsan may be administered cautiously in small doses and gradually increased.

THROMBO-ANGIITIS OBLITERANS'

This name was suggested by Buerger in 1908 for a disease characterised by acute inflammation of the deep arteries and veins, and sometimes a migratory inflammation of the superficial veins in the extremities. Thrombosis develops, and the vessels become occluded.

Ætiology.—The malady is found almost exclusively in middle-aged male Hebrews. The cause is unknown, but the pathological changes suggest that it is due to an infection. Syphilis is usually not present, the Wassermann reaction being negative. Excessive tobacco smoking has been suggested as a predisposing factor.

Pathology.—The deep vessels of the arms and legs, especially the latter, are occluded by thrombosis in various stages of organisation; their walls are traversed by vessels, and show a little inflammatory infiltration. In about a quarter of the cases this is associated with a migratory phlebitis in the superficial veins of the limbs. The condition is characterised by extensive progressive thrombosis, with organisation, with little inflammation of the vascular coats.

Symptoms.—The onset is gradual with pains in the feet and toes. The patient is unable to walk for more than a few minutes without severe cramp-like pain in the legs (intermittent claudication, see page 1019). The thrombi in the superficial veins, when they occur, are also very tender. Redness of the extremity, especially when in a dependent position, is often noted, while blanching occurs when the limb is raised. Diminution or loss of pulsation in the arteries, such as the radial or dorsalis pedis, is often present. In the later stages, the cramp-like pain becomes intense, and the disability in walking often leads to marked mental depression. Trophic changes in the skin, with gangrene, appear, and fissures and ulcers may occur.

Diagnosis.—(1) Raynaud's disease more often attacks females; the upper extremities are most affected; and X-Rays show marked atrophy of the bones of the hands. This is not present in Buerger's disease. (2) In erythromelalgia the limbs become red and flushed, but the arteries pulsate forcibly. Gangrene does not occur. (3) In gangrene due to Mönckeberg's degeneration, the calcified arteries may be well seen by means of the X-Rays.

Prognosis.—The course of the disease varies. Some cases progress rapidly, while others last for years. Gangrene may require high amputation of the limb.

Treatment.—As the cause is not known, there is no specific treatment. With regard to drugs, iodides and nitroglycerine are used. Gentle massage and passive exercises are useful. Ultra-violet therapy has been tried. Pain is relieved by rest in the recumbent position, and heat applied to the painful limb by electric pads or electric light baths is also useful. Ulcers of the legs should be treated surgically.

PERIARTERITIS NODOSA

Periarteritis nodosa is a rare complaint characterised by prolonged fever and the occurrence of nodular swellings, and in some cases aneurysms of the medium-sized arteries.

Ætiology.—Young adults are most commonly affected, and males more often than females. The cause is unknown. The Wassermann reaction is negative, but the pathological changes and course of the disease suggest an infectious agent.

Pathology.—The medium-sized arteries are usually affected, especially those of the heart, kidneys and intestines. A remarkably focal acute inflammation extends through all the coats of the artery, and within the lumen are often found thrombi, which may become organised. Aneurysmal dilatation is usually present. White or yellowish-white nodules, from the size of a pin's head to that of a pea, can be seen on the arteries. Owing to the alteration in the lumen of the vessels, necrosis and infarcts occur in the organs supplied.

Symptoms.—The disease may commence with bronchial catarrh, or with epigastric pain. There is tachycardia and irregular fever, with marked prostration. Acute abdominal pain may be caused by disease of the mesenteric arteries—indeed, even perforation of the intestine and peritonitis have followed. If the arteries of the heart are involved, evidence of myocardial disease will be present; and when the kidneys are affected, blood and casts appear in the urine. Occasionally bronchial asthma, cough and hæmoptysis have been noted. Later, in a small proportion of cases, nodular swellings, varying in size up to a pea, may be felt in the subcutaneous tissues of the abdomen, thorax and limbs. Examination of the blood shows anæmia and a moderate leucocytosis. Blood cultures are sterile.

Diagnosis.—This is extremely difficult, owing to the variable symptoms displayed. In most cases, a pyrexial infection, of unknown origin, has its nature revealed only at the post-mortem. Rarely, however, where a node was felt in the subcutaneous tissues and excised during life, the diagnosis has been made before death.

Prognosis.—In the great majority of cases death occurs within a few weeks to a few months after the onset of symptoms.

Treatment.—This is the same as that of any acute infection. Arsenic, mercury and quinine should all be tried, though the results up to now have not been encouraging.

ARTERIAL DEGENERATION

DEGENERATIONS OF THE INTIMA

(1) *Atheroma*

Definition.—Atheroma is a variety of arterial degeneration which affects and is almost confined to the intima. It is characterised by the accumulation of debris which is at first fatty and later becomes impregnated with

lime-salts. The Greek word was used by Galen to signify a swelling full of gruel-like material.

Ætiology.—There is no doubt that atheroma tends to increase with advancing age. Long life is a question of the blood vessels, and it has been well said that a man is only as old as his arteries. Occasionally the quality of the arterial tissue that the individual has inherited is poor, and a tendency to atheroma is often seen in all the members of certain families, thus showing the influence of heredity in the production of the condition. Much more commonly, however, atheroma results from the amount of wear-and-tear to which the vessels have been subjected. Atheroma appears as a secondary change in cardio-vascular hypertrophy, so that it tends to be more frequent in patients with hypertension than in other subjects of the same age. The affection is much more common in the male sex than in the female, and in subjects who have prolonged and laborious physical work. Moreover, it is much more common in the aorta than in the pulmonary artery, and when it does occur in the latter it is nearly always associated with high pulmonary tension, *e.g.*, in mitral stenosis and in pulmonary fibrosis. The severity of the disease increases with the length of time during which the high blood-pressure has existed. Over-eating and stress and strain of modern life are probably factors in the ætiology of the condition. The most important cause of atheroma is chronic poisoning. Acute degeneration of the media has been found after typhoid fever in young people, and has been caused experimentally by the injection of bacterial toxins. Chronic lead poisoning and gout are also ætiological factors. On the other hand, syphilis has no connection with atheroma, though the condition of the aorta known as syphilitic mesaortitis was for a long time confused with the chronic intimal degeneration we now know as atheroma. Disease of the kidneys probably has no direct relation with atheroma, though the high blood-pressure of chronic interstitial renal fibrosis and of secondary contracted kidney is an important factor in producing atheroma in the large elastic arteries.

Pathology.—Atheroma occurs in the large elastic and muscular arteries. The condition is usually most marked in the aorta. The coronary, the cerebral, the radial, the brachial and the temporal arteries are frequently affected. The condition may attack the retinal arteries. In the slighter degrees, minute yellow flecks or patches on the aorta may be observed by the naked eye. In the later stages, yellow plaques or buttons are conspicuous, and under the microscope masses of large fatty crystals, with a covering layer of fibrous tissue, are to be noted. Atheromatous plaques may ulcerate and the contents be discharged into the aorta, and thrombi are often deposited on the surface of these atheromatous ulcers. As the atheroma may be associated with degeneration of the media, a general dilatation of the aorta is very common. On the other hand, circumscribed aneurysm very rarely occurs, due to severe medial degeneration. The aortic valves are frequently affected by atheromatous degeneration, and aortic stenosis or aortic regurgitation may result. A yellow atheromatous patch is commonly seen on the anterior flap of the mitral valve. Atheroma often causes great narrowing of the lumen of the vessels, and eventually a thrombosis may form and complete occlusion result; this is the most dangerous result of atheroma; it frequently occurs in the large divisions of the coronary arteries, especially in

the anterior interventricular branch of the left, and is not uncommon in the vessels of the brain. With regard to the heart, atheroma has a most profound influence, owing to the fact that it is one of the commonest causes of fibrosis of the myocardium; but the chief danger is a sudden blockage of one of the coronary arteries, generally the anterior ventricular branch of the left coronary. In these cases, if death does not follow immediately, a sudden softening of the heart muscle (*myomalacia cordis*) may occur, and an aneurysm of the heart may result, and in certain rare cases actual rupture of the heart wall has followed—a broken heart. In the brain, atheroma results in cerebral thrombosis, and is the commonest cause of this condition in old people who have not had syphilis. Very commonly, however, especially in those cases of atheroma where the blood-pressure is raised, hæmorrhage may occur. In most cases of atheroma the kidneys are not involved, though occasionally atheromatous plaques may be found on the branches of the renal artery. Should, however, one of these plaques be large enough to cause much narrowing of an interlobar artery, a wedge-shaped red area of fibrosis in the distribution of the artery will occur. The renal changes, however, are relatively unimportant, and they rarely lead to symptoms during life.

Symptoms.—The blood-pressure is only raised if the atheroma happens to complicate cardio-vascular hypertrophy. In the aorta a diffuse dilatation, with pulsation in the supra-manubrial notch, may be present. The radial, the brachial and the temporal arteries are frequently irregularly thickened and tortuous, and can often be seen pulsating beneath the skin. Atheroma of the coronary arteries frequently gives rise to cardiac failure, and angina pectoris may occur; and sudden death is not uncommon, owing to a sudden thrombosis of a large branch. In the brain, hemiplegia usually results from hæmorrhage and more rarely from thrombosis. Ocular symptoms are rare in atheroma of the retinal arteries, which may be seen with the ophthalmoscope to be irregularly swollen and tortuous, but swelling of the optic disc and retinitis are not present.

Prognosis.—The course and prognosis are extremely uncertain. Circulation through the diseased vessels may proceed fairly satisfactorily for a long time, but thrombosis may occur with alarming suddenness, and with the direst results, if a cerebral or cardiac artery is affected.

Treatment.—The treatment of atheroma is unsatisfactory. Prophylaxis exists in the removal of the cause when possible. Great attention should be paid to diet, and repletion should be studiously avoided. Alcohol and tobacco should be taken with greatest moderation, and attention should be paid to regular exercise, and the action of the skin should be assisted by warm baths. It is doubtful if drugs are of value in the treatment of atheroma; possibly small doses of iodide of potassium may be of some use in absorbing the degenerative products and assisting in the circulation of the blood through the obstructed areas.

(2) *Other Degenerations allied to Atheroma*

Atheroma is characterised by an accumulation of fatty debris in the intima. There are closely allied intimal degenerations, in which this feature is absent.

In one form, which may be called *fibrotic degeneration*, muscle fibres, and

to a less extent elastic fibres, disappear after little or no fatty degeneration, and the intima becomes fibrotic. This degeneration may be found in any artery, but is very common in the smaller arteries, for instance, the interlobular and afferent arteries of the kidneys. In such small arteries atheroma is very rare.

Another modification, called *hyaline degeneration*, affects the ultimate arterioles in the kidney and other organs. In this form the muscle and elastic fibres disappear rapidly, and the intima becomes swollen and hyaline, and usually fatty. An intima is formed in the ultimate arterioles in almost all cases of cardio-vascular hypertrophy, but otherwise only in exceptionally severe medial degenerations. Consequently this hyaline degeneration is common in cases of persistently high blood-pressure, but is otherwise very rare.

Both these forms of intimal degeneration are of the greatest importance, because intimal fibrosis is much less focal than atheroma, and both forms, in affecting arteries of small calibre, lead even more than atheroma to a narrowing of the lumen sufficient to cause ischæmic destruction of the tissues.

DEGENERATION OF THE MEDIA

There are two forms of degeneration of the media, namely:—(1) That which is known as Mönckeberg's degeneration or ring calcification; and (2) fatty degeneration, the latter being the more common.

(1) *Mönckeberg's Degeneration*

This form of degeneration is accompanied by a deposition of lime-salts in the middle coat.

Ætiology and Pathology.—The cause is undoubtedly a senile degeneration of the elastic tissue and the muscle of the large muscular arteries, and a deposition of masses of lime-salts in the dying tissue. It has no relation to syphilis. This degeneration has been caused experimentally in animals by a great variety of toxins. In man the causation is obscure, but it is common in diabetes and in old people. The lime-salt is deposited, more or less symmetrically, within the media in plaques, which encircle part or all of the lumen. The affection is very common in the arteries of the leg below the bifurcation of the femoral; occasionally the radial and ulnar arteries are affected; rarely the aorta.

Symptoms.—The symptoms are coldness and œdema of the legs, as the result of defective circulation through them, and finally, and not uncommonly, gangrene results, this form of degeneration being usually present in senile cases and in cases associated with diabetes. The arteries feel like pipe-stems, and sometimes crackle when rolled beneath the finger. They can be well seen by means of the X-Rays.

Prognosis.—This depends partly upon the amount of gangrene present and partly upon the associated conditions.

Treatment.—It is clear that if amputation is undertaken a local amputation is of little value, and the limb should be amputated above the knee, as the arterial degeneration almost always extends to the bifurcation of the femoral artery.

(2) *Fatty Degeneration of the Media*

Fatty degeneration of the media occurs very commonly in all arteries. *It tends to occur in cases of high blood-pressure, and is consequently a common and important secondary complication of medial hypertrophy.* It is probably the result of toxins or lack of nourishment, and is frequently present in cases of severe anæmia. It also occurs in old age, and is associated with cardio-vascular hypertrophy. The muscle fibres become lost, being replaced by fibrous tissue. The vessel wall usually becomes weakened and is liable to rupture.

ARTERIAL HYPERTROPHY

Increase of the media of the muscular arteries and hypertrophy of the heart, particularly of the left ventricle, are invariably associated with persistent elevation of the blood-pressure. This anatomical indication of high blood-pressure may be called cardio-vascular myohypertrophy. Strictly speaking, myohypertrophy means increase in the size of already existing muscle fibres, while muscle hyperplasia is used to indicate an increase in the number of the fibres. In hypertrophy of the heart the individual muscle fibres are often found to be enlarged, while in the arteries there is an increase in the number of the muscle fibres. The term myohypertrophy is here used to include both these changes.

Ætiology.--Arterial hypertrophy is common in late middle age, and is by no means a senile change. In rare cases associated with chronic interstitial nephritis, it may occur in young children. It is more common in males than in females. Syphilis has no part in the causation of this condition, though, of course, it may be present in syphilitic cases; hypertension and cardio-vascular hypertrophy are comparatively uncommon in syphilitic vascular disease. Microscopical examination of the vasomotor centre in the medulla, and of the arteries which supply it, reveals no pathological changes, so that there is no direct evidence that changes in the bulb are the causes of the persistent vaso-constriction found in this condition. Arterial hypertrophy is the result of the circulation of poisons, which act as pressor substances and cause persistent contraction of the arteries and of the heart. The question as to whether it is the arteries or the heart which hypertrophy first has given rise to much controversy. It is probable, however, that they both hypertrophy simultaneously. These circulatory poisons may be enumerated as follows: (1) They may result from repletion due to over-eating and insufficient exercise, in which case they are absorbed from the intestines. It has been shown that certain diamines, the result of protein putrefaction, act as powerful pressor substances when introduced into the circulation. (2) They may arise from focal sepsis, e.g., in the teeth, the tonsils, the nasal sinuses and the genito-urinary tract. In some cases the removal of these foci of sepsis will permanently lower a persistent supernormal blood-pressure. (3) Endocrine disturbances may give rise to arterial hypertrophy and hypertension. This commonly occurs at the female menopause. The fact that these arterial changes may result from an artificial menopause produced by surgical means in comparatively young women points to loss of ovarian function as the causal factor. Myxœdema due to defective thyroid secretion is also associated with arterial myohypertrophy. Virilism due to tumour.

of the adrenal cortex is accompanied by hypertension, which may be due to an increased secretion of adrenaline, or to disturbance of the function of the other ductless glands. (4) Poisons may be introduced from without the body. Excessive smoking, chronic alcoholic excess and lead poisoning are frequent causes of arterial hypertrophy. (5) Prolonged mental strain and anxiety are also well known to lead to the condition, which has thus become much more common under the stress of modern civilisation. The isolation of adrenaline and its effect in raising the blood-pressure may supply the clue to the circulating substance in these cases. It has been shown that acute mental strain and fear result in an over-secretion of adrenaline. It is probable that the hereditary factor which is a feature in these cases may be explained by the inheritance of a nervous instability, and a disposition to worry constantly over trifles. (6) Pressor substances are also to be found circulating in the blood stream in renal disease. Here the kidneys fail to perform their function of eliminating poisons from the blood stream. Thus in gout, where defective renal function is an important feature, arterial hypertrophy is common. It is also found well marked in chronic interstitial nephritis, in secondary contracted kidney, and in the later stages of congenital polycystic disease of the kidneys. In all these conditions the diseased kidneys fail to eliminate from the blood stream certain metabolic poisons, which act as pressor substances, and the arterial change may be termed "nephritic myohypertrophy."

RELATIONSHIP OF CARDIO-VASCULAR HYPERTROPHY TO RENAL DISEASE.

—This may be summarised as follows: (1) Cardio-vascular hypertrophy may exist with no clinical evidence of renal lesion. On post-mortem examination, however, slight ischæmic changes in the kidneys are usually to be noted. (2) In other cases, cardio-vascular hypertrophy is followed by severe ischæmic changes in the kidneys (see Hyperpielic Kidney, p. 1290). In spite of severe destruction of renal tissue, there is no clinical evidence of renal disturbance other than slight albuminuria and hyaline casts in the urine. The renal efficiency tests give normal results. (3) Cardio-vascular hypertrophy may also be a sequel to chronic interstitial nephritis, or to secondary contracted kidney. With regard to the latter, it begins to appear when secondary contraction of the kidney follows chronic parenchymatous nephritis (see p. 1279). It is also well seen in the later stages of congenital polycystic kidneys. As in the course of years the kidneys gradually enlarge, owing to the increase in fluid in the cysts, the kidney substance between them gradually becomes destroyed by pressure, and as the kidneys fail to eliminate metabolic poisons, arterial hypertrophy develops.

Pathology.—As Sir George Johnson described in the year 1852, the condition is a true muscular hypertrophy. This increase in muscle occurs in the heart (mainly in the left ventricle), and in the media of the muscular arteries. In the later stages of the malady, one or both of the layers of the intima hypertrophy in arteries in which an intima is normally present, and similar layers are developed in arteries in which no intima normally exists. In the muscular arteries an intima is only found normally at the orifices of the branches. In the course of time, this being earlier in older people, there is a tendency to degeneration in the hypertrophied muscular tissue, the muscle fibres disappearing, with or without fatty degeneration. These degenerative changes give rise to two distinct alterations in

the arterioles: (1) Owing to the loss of muscle fibres in the hypertrophic media, the wall of the vessel becomes weak, is constantly expanded and finally ruptures, so that hæmorrhage from various organs is a very common complication of cardio-vascular hypertrophy. (2) In the smaller arteries, atheromatous, fibrotic or hyaline degeneration in the intima (*vide supra*) leads to narrowing and obliteration of the lumen. As a result, a patchy ischæmic fibrosis of the organ takes place. According to this view, the cardio-vascular hypertrophy is antecedent to the degenerative changes in the vessel wall, the clinical manifestations of the former, such as hypertension, preceding those of the latter.) The muscular arteries are those chiefly affected. The radial and temporal arteries, and the arterioles of most of the organs of the body, are involved. In the case of the cerebral arteries, the perforating branches of the middle cerebral most frequently rupture, especially the lenticulo-striate branch. Hæmorrhage may also take place from the kidneys, the stomach, the intestines and the nasal mucous membrane. In cases of simple hyperpiesia, secondary degeneration of the arterioles tends to appear rapidly, and this leads to ischæmic fibrosis (see Hyperpietic Kidney). In cases where the cardio-vascular hypertrophy is the sequel either of chronic interstitial nephritis or of secondary contracted kidney, ischæmic changes in the kidneys are associated with the inflammatory changes described under these diseases respectively. In the heart the most striking change is the muscular hypertrophy, the left side being very much more involved than the right; the left ventricle may be even two or three times thicker than normal. In the aorta there may be little or no change, but patches of atheroma are not uncommon. The aortic valves are rarely affected. The primary and essential pathological change in arterial hypertrophy is an increase of the muscular fibres in the media and intima of the muscular arteries and arterioles. Consequently it is inadvisable in describing this form of arterial change to make use of the term arterio-capillary fibrosis (Gull and Sutton).

Symptoms.—In cardio-vascular hypertrophy the vessel wall is felt to be uniformly thickened—the so-called “whip-cord” artery. The degree of hardening of the arteries is found on palpation to vary at different times. The artery feels hardest when the vessel is most contracted and consequently smallest. As the muscular arteries are those chiefly affected, the radial, the brachial and temporal arteries are involved. The systolic blood-pressure in cases of simple hyperpiesia varies from 170–200 mm.; in cases associated with chronic interstitial nephritis it may reach even 300 mm. or more; and in secondary contracted kidney and in polycystic disease of the kidneys it varies between 160 and 220 mm. Symptoms of cardiac hypertrophy are common in the early stages. In some cases cardiac hypertrophy is followed by dilatation, with its attendant symptoms. Headache, of a throbbing and bursting character and generally in the occipital region, is an early symptom of arterial hypertrophy, and giddiness and fullness in the head are frequently complained of. Transient paralysis may occasionally be met with, and this has been attributed to spasm of the hypertrophied arteries. Later on, cerebral hæmorrhage, with the production of hemiplegia, may occur. Albuminuria and casts in the urine may be found, while profuse renal hæmorrhage may occur. Uræmic symptoms do not occur unless the condition is complicated by true nephritis. Gastro-intestinal symptoms are often present.

1018 DISEASES OF THE CIRCULATORY SYSTEM

The patient may first complain of dyspepsia. A chronic diarrhoea without obvious cause in an elderly man should lead to a careful examination of the arteries and kidneys. Bronchitis and emphysema may mask a cardio-vascular hypertrophy, and the enlargement of the heart may be overlooked ; it is only by careful examination of the blood-pressure and urine that the underlying conditions can be recognised. The changes in the fundi are numerous and characteristic. The retinal arteries are thickened, and on ophthalmoscopic examination often show a glistening light along their course—the so-called “silver wire” arteries, due to the reflection of light from the thickened artery. If one of the thickened arteries is examined in the neighbourhood of the optic disc, it may be seen to cross a retinal vein and in so doing obstruct the flow of blood through it, leading to distension of the peripheral part of the vein. Retinal hæmorrhages, which are often flame-shaped, are occasionally to be noted, due to fatty degeneration in the hypertrophied muscular tissue. If the cardio-vascular hypertrophy is due either to chronic interstitial nephritis or to secondary contracted kidney, hæmorrhages are much more common, and also further changes in the fundi, due to either of these affections respectively—described elsewhere—are to be noted. Intermittent claudication is not uncommon in these cases.

Prognosis.—The prognosis depends very largely on the degree of renal involvement. In hyperpiesia the condition may last for many years and only be terminated by hæmorrhage into the brain, the ischæmic fibrosis of the kidney, which accompanies it, being of no clinical importance. If, however, there is evidence that the cardio-vascular hypertrophy and high blood-pressure are complicated by true nephritis, the condition is a grave one and uræmia may ensue ; and when well-marked albuminuric retinitis is present death usually occurs within six months, though very rare cases have been recorded where a certain amount of ocular change has persisted for years.

Treatment.—The first indication is to remove the cause of the condition as far as possible. Thus, gouty tendencies should be corrected by the administration of alkalis and intestinal antiseptics, such as sodium benzoate or diluol. All sources of focal sepsis, whether in tonsils, teeth, nasal sinuses or genito-urinary tract, should be carefully sought for and, if found, removed. Moderation in food and drink, with regular exercise and care in promoting diaphoresis, is essential. Turkish and vapour baths may be given cautiously. The administration of a brisk purgative pill once a week, and the use of a mild saline purgative each morning are indicated. Nitroglycerine and the nitrites are useful in moderate degrees of increased blood-pressure, though where the blood-pressure is very high they rarely produce any permanent benefit. In these latter cases the administration of thyroid extract has been successful in reducing the pressure to a more reasonable level ; while in acute crises the abstraction of one pint of blood from the arm has often saved life.

ARTERIAL INFILTRATION

The commonest form of infiltration is amyloid infiltration.

Ætiology.—Amyloid or lardaceous disease occurs in cases of long sup-puration due to pyogenic organisms, and is frequently associated with the

secondary pyogenic infections which occur in tuberculosis of the bones and joints, in chronic syphilitic ulceration, and in actinomycosis.

Pathology.—The amyloid substance is extracellular and is deposited beneath the endothelium of capillaries, the reticulum of adenoid tissue and the pulp of the spleen, and in the smaller arteries and veins, especially in their middle coats. The affected organs are firm to the touch and have a waxy appearance. The amyloid substance can be demonstrated macroscopically by pouring tincture of iodine on the affected organ, the waxy material being stained a deep mahogany colour. Microscopically, an iodine staining may be used, or a methyl-violet stain, which colours the amyloid substance pink and the parenchymatous cells blue. In the kidney, the small arterioles in the glomeruli, those around the convoluted tubules and those in the medulla, are first attacked. In the intestine, the arterioles in the villi stand out clearly. There are two forms of amyloid infiltration of the spleen: the diffuse waxy spleen, where the venous sinuses are outlined and the central artery of the Malpighian capsule is affected; and the sago spleen, where the Malpighian capsule is greatly enlarged by the amyloid infiltration—its central artery is untouched, but its branches into the capsule are greatly swollen by the waxy material. In all these organs the parenchymatous cells are unaffected directly by the amyloid infiltration, but in the later stages necrose, owing to interference with their nourishment.

Symptoms.—The patient is pale, but often has a waxy complexion with a bright colour in the cheeks. Chronic, profuse and painless diarrhoea is common. The urine contains a large quantity of albumin, and is usually fair in amount and of low specific gravity. The liver and spleen are enlarged, and ascites and oedema of the legs are often present.

Prognosis.—If the chronic suppuration can be cured, the condition may sometimes disappear; but in the majority of cases this is not possible, as the septic condition is engrafted on to a chronic tubercular or other granulo-matous condition, which is almost always impossible to eradicate.

Treatment.—This consists in trying to remove the cause.

INTERMITTENT CLAUDICATION

The term "intermittent limp" or claudication is applied to a condition in which severe pain, in one or both legs, comes on after walking for a certain distance.

Ætiology and Pathology.—In the large majority of cases this syndrome occurs in elderly men, who have well-marked calcification of the middle coat of the arteries of the lower limbs (Mönckeberg's degeneration, *q.v.*). In rarer cases it may be present in arterial hypertrophy or thrombo-angiitis obliterans (*q.v.*). It may be associated with gout, diabetes, syphilis and excessive indulgence in tobacco.

The symptoms are due to the arteries of the leg being unable to supply to the muscles the increased flow of blood that the limb requires during walking.

Symptoms.—The characteristic pain comes on after walking a certain distance. It may be accompanied by cramp in the calves, and also by numbness or tingling sensations. It causes the patient to limp and finally

to stop. After resting for a minute or two, he is able to continue walking, but the symptoms again recur after he has walked for a further period. In nearly all cases there is absence of pulsation in the dorsalis pedis artery, or in the posterior tibial of the affected limb, which often shows signs of circulatory disturbance, being swollen, congested and mottled, while the toes may be white and cold. The amount of calcification in the arteries, which is often very extensive, may be determined by X-Ray examination. In many cases dry gangrene of the limb has supervened.

Prognosis.—The prognosis is bad, but the attacks may persist for years before more serious results, such as gangrene, appears.

Treatment.—Exercise must be limited, and the patient warned to move slowly and avoid hurrying in his walks. Diathermy has been used to relieve the pain. Heart muscle extracts and preparations of the pancreas given hypodermically have been tried, but without much success. Dry gangrene may require amputation of the limb, and when threatened may be relieved by removing the sympathetic nerves round the femoral artery.

ANEURYSM

Definition.—The word aneurysm is derived from the Greek to widen or dilate, and may be said to include any dilatation of an artery.

Aneurysms are generally divided into—

1. **TRUE ANEURYSMS**, in which the walls of the dilatation are formed by the coats of the artery. These may again be divided into—

(a) *Diffuse aneurysm*.—These are general dilatations of an artery. The dilatation is relatively slight, and is of no clinical significance except that it indicates medial degeneration. The artery is sometimes tortuous in addition, the so-called cirroid aneurysm.

(b) *Circumscribed aneurysm*.—These are limited to a segment of an artery, or to a part of its circumference.

(c) *Dissecting aneurysm*, caused by the splitting of the coats of the artery, the blood having passed through the lumen into the wall of the artery, separating one coat from another.

(d) *Arterio-venous aneurysm*, in which there is a communication between an artery and a vein. There are two varieties in this group—(1) aneurysmal varix, and (2) varicose aneurysm.

2. **FALSE ANEURYSMS** are those following a wound or rupture of an artery, with the formation of a diffuse or circumscribed hematoma, and are bounded by tissues external to the wall of the artery.

A true aneurysm frequently ruptures and gives rise to a false aneurysm and the resulting structure is known as a mixed aneurysm.

Ætiology and Pathology.—The two main factors in the causation of aneurysm are—(1) loss of the muscular and elastic fibres in the wall of the artery; (2) strain. The latter may be brought about by either high arterial tension or by repeated and prolonged muscular effort. The importance of strain as a causal factor is borne out by the fact that aneurysm is much more frequent in men than women—about five to one—and occurs more frequently in the fourth decade of life than at any other period. It also occurs much

more frequently in hard manual workers, such as dock labourers, soldiers and sailors. *By far the most common cause producing weakening of the large elastic arteries is syphilitic inflammation. In cases of persons dying of aneurysm, examination of the aorta in the neighbourhood of the aneurysm will, in a large majority of cases, reveal mesaortitis* (see page 1008). Aneurysm may also result from erosion of the walls of the arteries in cases of septic endocarditis—the so-called mycotic aneurysm. Frequently these aneurysms are multiple. Extensive growth of streptococci and septic granulations may be seen in the neighbourhood of the dilatations.

Aneurysm may also be the result of congenital defects in the media of the vessel, which is very commonly seen about the circle of Willis, at the junction of the anterior communicating artery with the anterior cerebral. The aneurysms vary from about the size of a pin's head to that of a pea, and not infrequently their rupture gives rise to a diffuse subarachnoid hæmorrhage, the origin of which is often overlooked unless careful search is made for the aneurysm. Congenital aneurysm has also been described in the aorta, at the point of insertion of the ductus Botalli, and in cases of coarctation of the aorta, in which condition there is great narrowing of the aorta just below the origin of the left subclavian artery.

Loss of support by surrounding tissues also appears to lead to the production of aneurysm, e.g. at the base of a gastric ulcer a small aneurysm often projects as a nodule and is liable to rupture. Peptic erosion may also be a cause of weakening the walls of such arteries. In the cavities of the lungs, occurring as the result of pulmonary tuberculosis, it is quite common to find an aneurysm on the walls of the arteries lying in such cavities.

It is very doubtful if external trauma alone is ever the cause of true aneurysm, but injury to the artery by penetrating wounds by knives or bullets may certainly cause it.

Slight medial degeneration leads to diffuse aneurysm, and severe medial degeneration may cause circumscribed aneurysm. It is the usual cause of circumscribed aneurysms of muscular arteries, such as the popliteal, but is a very rare cause of circumscribed aneurysm of the aorta. Atheroma itself does not lead to aneurysm, but it may be complicated by medial degeneration. Continued high blood-pressure, as in other forms of aneurysm, is an important contributory factor in the formation of a diffuse dilatation of the aorta.

One of the most striking appearances in an aneurysm is the coagulation of blood in the sac itself. This does not occur in diffuse dilatation of the aorta, but in those cases of sacculated aneurysm where the wall has become roughened. The sac becomes lined with fibrinous deposits, and occasionally an aneurysm may be cured by the deposition of successive layers of fibrin, so that the sac becomes almost completely filled. On the other hand, thrombus in aneurysms may form emboli and so lead to infarcts. Again, in many fatal cases of aneurysm, rupture and hæmorrhage have taken place, the deposition of fibrin having failed to prevent the blood reaching the surface. Rupture may take place externally, or into any of the hollow viscera or the serous cavities. Rupture into the pleura is common, as also is rupture into the trachea or into the œsophagus. In these cases, death is usually sudden, though oozing may have taken place some time before the final rupture. When the hæmorrhage forces itself into the connective tissues or muscles, it takes place much more slowly, and in the cases of the limbs may allow time

for treatment. An aneurysm often exercises pressure on the other organs and structures in its neighbourhood. The heart is displaced away from the aneurysm, and the blood vessels are often narrowed so that circulation through them is impeded. The trachea, the bronchus, the œsophagus and the nerves passing near the aneurysm also suffer. When the aneurysm meets bony tissues, absorption of the bone takes place and the vertebræ are frequently eroded in this way, the bone being absorbed more rapidly than the intervertebral cartilage. When the aneurysm presses against the anterior surface of the chest, the ribs and sternum are pushed forward and finally are absorbed and perforated.

I. ANEURYSM OF THE THORACIC AORTA AND ITS BRANCHES

These are two types—(1) The diffuse aneurysm, or general dilatation, which occurs in medial degeneration of the aorta ; and (2) the circumscribed, usually saccular, aneurysm, almost always the result of syphilitic inflammation.

DIFFUSE ANEURYSM (GENERAL DILATATION)

Symptoms.—In diffuse aneurysm of the aorta the enlargement is extensive, but never reaches a very great size. The symptoms of this form of dilated aorta are generally due to atheroma and the medial degeneration which accompanies it. Very often there is interference with the coronary circulation, and this leads to diminution of the circulation of blood through the heart and consequently to cardiac pain. The aorta may sometimes be felt pulsating in the supra-manubrial notch, and the X-Ray photograph will show general dilatation of the aortic arch. When the aortic ring is not stretched, the dilatation of the aorta beyond it may lead to the formation of a systolic murmur. Occasionally these patients die suddenly, on account of thrombosis of an atheromatous branch of a coronary artery. Provided there is no aortic regurgitation or coexisting coronary disease, patients with dilated aorta may live for many years without serious discomfort.

CIRCUMSCRIBED ANEURYSM

Symptoms and Diagnosis.—ANEURYSM OF THE ASCENDING PART OF THE ARCH OF THE AORTA.—An aneurysm of the ascending part of the arch tends to grow forward and outwards, and to produce a pulsating tumour which is palpable and audible at the level of the second or third interspace, and is hence often called the *aneurysm of physical signs*. It often erodes the ribs and sternum. The tumour is tender and is often the seat of pain, which may be constant but is increased by exertion. A soft systolic murmur may be heard over it. If the part adjacent to the aortic valves is affected, the aortic ring may be dilated and aortic regurgitation will take place. There will then be hypertrophy and dilatation of the left ventricle, with an aortic diastolic murmur, and the symptoms will be those of aortic regurgitation.

The pressure effects produced by an aneurysm of the ascending aorta are as follows: The heart is displaced downwards and to the left. The superior vena cava is pressed upon. This may result in cyanosis of the head

and neck, and œdema of the arms, and enlarged veins may frequently be seen coursing over the front of the thorax. Occasionally the aneurysm may rupture into the superior vena cava, in which case the symptoms noted may come on quite suddenly and are very marked. There is often a systolic thrill, and on auscultation a continuous murmur, which is increased during systole, is of great diagnostic value. The aneurysm may press upon the right bronchus, causing a chronic cough, due to irritation of the bronchus and stasis of its contents, and deficient or absent breath sounds over the upper lobe of the right lung. The aneurysm may occasionally press upon the pulmonary artery and in rare cases actually open into it, causing great dilatation of the right ventricle and auricle. Such aneurysms may present themselves to the left of the sternum rather than in the usual place, the right. In rare cases aneurysm of the ascending aorta has perforated the right ventricle; the right or left auricle occasionally has ruptured into the pericardial sac. When the aneurysm comes forward it may irritate the pleura; and in some cases a loud pleuritic rub, audible over the aortic area, may be one of the early signs. Not uncommonly this form of aneurysm may rupture into the pleura and occasionally it ruptures externally.

ANEURYSM OF THE TRANSVERSE ARCH OF THE AORTA.—As the arch of the aorta passes from right to left it also passes from before backwards, and consequently aneurysms arising from the transverse and descending parts of the aortic arch are situated more deeply in the chest than those arising from the ascending portion. Aneurysms of the transverse and descending parts of the aortic arch have been called by Broadbent *aneurysms of symptoms*, because their presence has often to be inferred by the pressure symptoms which they produce, while a pulsating tumour is only present in the very late stages and may never appear at all during the whole course of the disease.

1. *Pain.*—Pain is one of the most common and earliest symptoms of aneurysm. It may often be anginal in character; that is to say, it may occur in the cardiac region or across the back and pass down the left arm and be very severe. This form of pain occurs when the aortic valve is affected and when the ascending aorta is distended. When, however, the transverse arch is affected the pain is sometimes felt on the left side of the neck and even in the occipital region. It is probable that this pain in the neck is a reflected pain from the spinal cord, resulting from the abnormal afferent impulses reaching the cervical spinal cord as a result of the distension of the transverse arch. A boring, persistent pain in the chest is probably the result of direct pressure of the aneurysm.

2. *Respiratory symptoms.*—Dyspnœa is common in aneurysm, and is usually caused by pressure upon a bronchus. There is often stridor, which in this case is heard both in inspiration and in expiration. Hæmorrhage also occurs as a result of leaking of an aneurysm through the bronchus. It may at first be slight, but often a huge gush of blood supervenes, causing death. It is said that reflex irritation of the vagi will occasionally cause bilateral adductor spasm of the vocal cords and marked dyspnœa. In this case the stridor is only heard with inspiration and disappears if a little chloroform is inhaled. Patients with aneurysm often have a ringing, rough, brassy cough. If the pressure on the bronchus has been gradual, secondary changes occur in the lung. Dr. Newton Pitt has brought forward evidence

to show that compression of the left bronchus in the early stages produces over-distension of the left lung with diminished or absent breath sounds. This may be so great as to lead to a suspicion of pneumo-thorax; later on bronchitis occurs with dilatation of the bronchus with expectoration of purulent phlegm. Pressure on the trachea may occasionally be observed in cases of aneurysm of the aortic arch, the larynx being drawn downwards and backwards with each cardiac pulsation. A very important physical sign was described by Surgeon-Major Oliver and is known as *tracheal tugging*. The patient should be placed in the erect position, and directed to close his mouth and elevate his chin. The cricoid cartilage should be grasped between the finger and thumb and gentle steady upward pressure be made upon it. If aortic dilatation or aneurysm exists, the pulsation of the aorta will be distinctly felt transmitted through the trachea to the hand. This is a valuable sign, and often occurs in aneurysm before other symptoms are evident. Occasionally a systolic murmur may be heard in the mouth when the patient compresses his chest with his mouth wide open. Dr. Sansom has pointed out this tracheal whiff may be rendered distinctly audible with a binaural stethoscope when the end is placed in the mouth with the lips closed over it. It is either the aortic systolic murmur produced at the mouth of the sac, or the result of driving the air out of the windpipe during systole by the pressure of the aneurysm.

3. *Pressure on nerves.*—(a) The left recurrent laryngeal nerve.—This nerve courses round the arch of the aorta and passes up behind it, and is consequently often involved in aneurysm of the transverse arch. The abductor fibres of the recurrent laryngeal nerves succumb to the effect of pressure before the adductor fibres and consequently the vocal cord is at first in the position of adduction. During respiration, the right vocal cord moves up to and meets the adducted left vocal cord and respiration is unaffected. During phonation, the right vocal cord again comes up to and meets the left vocal cord, and the voice may be quite normal. It is therefore clear that a laryngoscopic examination may reveal the early stage of pressure on the left vocal cord before there has been any alteration in the voice. As the pressure increases, the adductor muscles are affected and the left vocal cord remains motionless in the cadaveric position half-way between full inspiration and full expiration. The voice is now hoarse, and it not uncommonly happens that hoarseness is the first symptom for which the patient presents himself. (b) Pressure on the sympathetic nerve.—Pressure upon the sympathetic nerve causes first of all irritation and later on a paralysis of the cervical sympathetic fibres. When the sympathetic is irritated, the pupil on the same side is dilated, and this is accompanied by slight protrusion of the eyeball, slight retraction of the upper eyelid, together with sweating and flushing of the same side of the face and ear. When the cervical sympathetic is paralysed, the pupil is smaller than on the opposite side, the eyeball is sunken into the orbit, and there is a slight degree of ptosis. Unequal pupils in aneurysm are, however, frequently found without any of the other symptoms of sympathetic irritation or paralysis, and in these cases another explanation must be found. Doctors Wall and Walker suggest that the difference in the pupils is due to pressure of the aneurysm upon the arteries passing to the neck. They have shown that in a condition of low blood-pressure the pupils are dilated, whilst in a

condition of high blood-pressure they are contracted, and that pressure upon one common carotid will cause dilatation of the pupil on the same side. They point out that under these conditions the dilated pupil is constantly on the same side as the smaller temporal pulse, and they consider that the dilated pupil and the small pulse are due to the same cause, namely, pressure upon the arteries supplying that side of the neck. Unequal pupils also occur as the result of syphilitic disease of the nervous system. We may get bilateral pin-point pupils, or the pupils may be unequal and irregular in outline. In both cases the reaction to light is lost, while the reaction to accommodation remains. I have seen a case where a syphilitic aneurysm occurred coincidently with a syphilitic paralysis of one third nerve, and in this case the pupil was dilated and the other symptoms of paralysis of the third nerve were present. (c) Pressure upon the intercostal nerves occasionally results from an aneurysm which presses backwards and erodes the vertebræ and posterior portions of the ribs. In these cases the pain is very severe along the affected nerves. In the distribution of the nerve itself the skin may be anæsthetic—the so-called *anæsthesia dolorosa*. (d) In some cases the aneurysm presses upon the brachial plexus, shooting pain occurring in the head and neck and down the right arm.

4. *Pressure upon the branches springing from the aorta is not uncommon.*—This may result in the absence of one radial or temporal pulse, or inequality between the two pulses. If the innominate artery is pressed upon, the right radial and temporal arteries may be small and imperceptible, while in an aneurysm of the transverse arch of the aorta, the left subclavian artery is compressed, in which case the left radial pulse may be affected. A sphygmographic tracing is often of value in demonstrating the difference between the two pulses, and a forced expiration, by increasing the intrathoracic pressure, will often accentuate the difference between the two sides. When the pulses are markedly unequal, the blood-pressure is also diminished on the side of the feeble pulse; a difference of pressure of over 30 mm. between the two sides is strongly in favour of aneurysm.

5. *Pressure on the œsophagus may result in slight difficulty in swallowing, but the dysphagia is very rarely complete.*—Occasionally the aneurysm may ulcerate into the œsophagus, until at last death takes place from a sudden rupture.

ANEURYSM OF THE DESCENDING PORTION OF THE ARCH.—In these cases the sac frequently projects backwards and erodes the vertebræ from the third to sixth thoracic, causing great pain and occasionally compression of the spinal cord, resulting in paraplegia. Dysphagia is common, and sometimes a tumour appears in the region between the scapula and the spine, and may attain a very large size.

ANEURYSM OF THE DESCENDING THORACIC AORTA may occur close to the diaphragm. Aneurysm of this form is frequently overlooked, pain in the back being the most prominent early symptom.

ANEURYSM OF THE INNOMINATE ARTERY.—This is not uncommon. It forms a pulsating tumour, which can sometimes be felt above the right clavicle, and nearly always produces marked diminution in the right radial and temporal arteries. In this form of aneurysm, paralysis of the right recurrent laryngeal nerve occurs not infrequently, the right vocal cord being paralysed instead of the left.

Inspection.—This is most essential. Abnormal pulsation should be looked

for in the thorax, and can often be seen when the patient is looked at obliquely in a good light. Posterior pulsation is generally observed to the left of the spine. Enlarged veins over the chest, suffusion of the face, and alteration in the pupil may be noted. The apex-beat is often dislocated from its normal position, especially when the sac is large, this being due to pressure of the aneurysm on the thorax; the heart itself is seldom hypertrophied, unless there is a leakage through the aortic valves.

Palpation.—Palpation may reveal the area and degree of the abnormal pulsation. There may only be a diffuse impulse, but if the sac has perforated the chest-wall, a forcible heaving and expansile impulse may be felt. Occasionally a diastolic shock is to be noted. This has been thought by some to be due to the forcible closure of the aortic valves producing an effect within the aneurysmal sac; another explanation is that the contraction of the heart draws in the ribs during systole at the point where they are adherent to the aneurysm and the diastolic shock is produced by the elastic recoil of the ribs and costal cartilages. Occasionally a systolic thrill may be felt.

Percussion.—A dull area may in some cases be made out in the second right interspace in cases of aneurysm of the ascending aorta. Much more rarely an aneurysm of the arch may press forwards and to the left, and produce dullness below the left clavicle. Pressure upon a bronchus may at one period result in hyper-resonance from lung distension, and later, owing to absorption of air in the lung, the percussion note may become dull.

Auscultation.—There may be no murmur, even in a large aneurysm, but a systolic murmur is not uncommonly present. When both systolic and diastolic murmurs are heard, aortic regurgitation is present in addition to the aneurysm. Accentuation of the aortic second sound is the most reliable auscultatory sign of aneurysm.

Reference has already been made to alteration in the radial and temporal pulses. Occasionally in a large aneurysm of the descending aorta there may be absence of pulsation in the abdominal aorta and peripheral arteries of the legs, the dilatation of the thoracic aorta being sufficient to convert the intermittent into a continuous stream.

Tracheal tugging is another very valuable physical sign of aortic aneurysm, especially in the differential diagnosis of aneurysm from tumour.

Examination by the Röntgen rays is most important in every case where aneurysm is suspected. The chest should be examined from the anterior, the posterior and the right oblique positions. In the last position, most valuable information as to the state of the aortic arch can be obtained. With the fluoroscope the pulsation of the tumour and its relation to the aorta may actually be seen, but photographs should always be taken, both in the anterior-posterior and oblique positions, as much information is obtained from the density of the shadow cast by the aneurysm. If the latter is very dense, it can be reasonably inferred that deposition of the laminated clot has taken place within the sac.

Complications and Sequelæ.—The main complication, bringing about a fatal termination, is rupture, which may take place either externally, into the pericardium, into the pleura, into the œsophagus, into the bronchus, or into the lung tissue itself. Pressure on the trachea, causing stridor and respiratory obstruction, is a very distressing complication. Bronchitis may occur during the course of the illness, and may be recovered from more than

once. Broncho-pneumonia and gangrene of the lung not infrequently occur when there is pressure upon a bronchus, and empyema may also result. Tuberculosis of the lung may coexist with aneurysm, but death from hæmoptysis, the result of perforation of a deep-seated aneurysm into the bronchus, has often been mistaken for the profuse hæmorrhage of tuberculosis. Cardiac failure is responsible for a large number of deaths. This may be the result of exhaustion, or of displacement of the heart, or of interference with the circulation through the coronary arteries; in other cases it is due to the aortic regurgitation. Cerebral embolism sometimes occurs in cases of aortic aneurysm, a portion of the clot within the artery becoming displaced and passed up to the brain.

Course.—Most cases live from 2 to 3 years from the time when the first symptoms have appeared. Occasionally life may be prolonged for several years by treatment. In rare cases spontaneous cure may be obtained by deposition of laminated clots within the cavity of the aneurysm, but this result is comparatively rare.

Diagnosis.—Intrathoracic aneurysm is often difficult to diagnose from intrathoracic new-growth. In both there may be an externally projecting tumour, but in aneurysm the pulsation may be seen to be expansile. The diastolic shock present in aneurysm is absent in a case of new-growth. Systolic murmurs may occur in both conditions, but the ringing aortic second sound is of great importance, and is rarely heard in tumours. Tracheal tugging is in favour of aneurysm, while progressive wasting and enlargement of glands in the neck are in favour of new-growth. Aneurysm, as a rule, occurs in apparently healthy men under 55 years of age, whereas malignant growth in the chest occurs either in early life or advanced years, and is associated with emaciation and pallor. In aneurysm there is a greater likelihood of the pupils and pulses being unequal, while in new-growth œdema of the upper extremities and chest-wall is not uncommon. In all doubtful cases an X-Ray examination should be made, and will nearly always clear up the diagnosis between the two conditions. Clinical evidence of infection by syphilis and a positive Wassermann reaction are important in diagnosis.

A violently pulsating thoracic aorta, either in association with aortic regurgitation or with violent throbbing of the heart, may lead to the unfounded suspicion of an aneurysm.

In cases where an empyema is pointing on the left side in the region of the heart, the tumour may pulsate. The throbbing is usually diffuse and widespread, and there is a coexistence of a pleural effusion. Exploration with a fine needle will usually settle the diagnosis. It must, however, be remembered that occasionally an empyema may be the result of extension of septic trouble from a bronchus which has become compressed by an aneurysm.

Prognosis.—In aneurysm this is always difficult. Complete cure is very unlikely, although pain and other unpleasant symptoms and physical signs may give way to treatment. The presence of aortic regurgitation is unfavourable, while an aneurysm progresses much more slowly in people of a placid disposition and those who lead a quiet life. Even in cases where treatment has apparently been most successful and pain and dyspnoea have been apparently relieved, sudden death not uncommonly occurs from rupture of the sac.

Treatment.—The recognition of the fact that the main cause of

aneurysm is the weakening of the wall by syphilitic mesaortitis has brought anti-syphilitic treatment into the forefront of modern treatment of aneurysm of the thoracic aorta. Mercurial inunctions and injections have been but little tried, but in many cases a good deal of benefit has been observed. The iodides have been given in aneurysm for many years—long before syphilis had been recognised as a cause of the condition. The most striking effect of iodide is the relief of pain, and this may be obtained by even small doses, such as 5 grains three times a day. In all cases, however, large doses, such as 20 grains three times a day, should be given a trial. Dr. de Haviland Hall, in his lectures on intrathoracic aneurysm, states that it is inadvisable to give salvarsan; but I have given this drug intravenously in several cases with marked success. In two cases where the patients appeared to be almost moribund from respiratory complications, owing to pressure, the administration of salvarsan was followed by distinct improvement, and both these patients have remained comparatively well, one for 3 and the other for 4 years.

Efforts to produce clotting within the sac should be tried in early cases of aneurysm. Of these the best known is Tufnell's method—that of a complete rest and restricted diet. The patient must lie in a perfectly quiet and secluded room, and the treatment should be pursued for several months. He should not consume more than 10 ounces of solid food and 8 ounces of fluid per diem. Iodide of potassium should not be given during this period, as it increases thirst and makes it impossible to limit the amount of fluid. Few patients put up with such a rigid diet and rest, but an endeavour should be made in an early case to attempt this method. Secondly, the administration of lime-salts, such as the chloride or lactate of calcium, should also be tried, in an endeavour to promote clotting within the sac. Twenty grains of calcium lactate three times a day may be given for the first 3 days of a week, and be omitted for the remaining 4 days. Normal horse serum may be given in conjunction with the calcium lactate, either by the mouth, per rectum or hypodermically. The gelatin treatment, introduced by Lancereaux, consists in the hypodermic administration of 50 c.c. of a 2 per cent. solution. Unfortunately several deaths have occurred, owing to the gelatin solution having become infected by the tetanus bacillus. It is very doubtful whether the treatment has had much success. It has been suggested that the effect on the blood may be due to the amount of calcium the gelatin contains.

Many patients with intrathoracic aneurysm do better if they are allowed to follow their general avocations, provided their work be not too strenuous for body or mind. Patients should be cautioned to take things as easily as possible, to avoid alcohol, eat with great moderation, and avoid any sudden exertion. A certain amount of tobacco may be smoked.

Special symptoms may have to be treated. For severe pain, cyanosis and dyspnoea, venesection will often give marked relief. Amyl nitrite and iodide of potassium are of great service in relieving the anginal pain of aneurysm. Severe paroxysmal dyspnoea is nearly always due to direct pressure on the trachea; both inspiratory and expiratory stridor are present. The inhalation of chloroform does not give relief, and tracheotomy is quite useless. It has been stated that in some cases there is a bilateral abductor spasm of the vocal cords, due to irritation of the vagi—a very rare condition. If present, relief will probably be obtained by chloroform. Intubation of

the larynx is generally preferable to tracheotomy ; in fact, the latter operation should never be performed to relieve the dyspnoea of aneurysm.

Surgical Treatment.—This may be considered under four heads—(1) ligature of the vessels arising from the arch of the aorta ; (2) the passage of wire into the sac with or without galvanism ; (3) needling the sac ; and (4) ligature of the neck of the sac.

Ligature of vessels has been of little service in the case of aneurysm of the aorta. In aneurysm of the innominate artery, combined simultaneous ligature of the right common carotid and subclavian arteries may be tried, but even this may be insufficient to prevent the flow of blood through the sac. Moore's method of introducing silver or zinc wire into the sac through a cannula has been used, but the best results have been in cases of abdominal rather than intrathoracic aneurysm. Puncture of the aneurysm and scratching its wall with the point of a needle, as advocated by Sir William McKwen, has been partially successful in several cases. Ligature of the neck of the sac may be undertaken when it appears to be small, but suitable cases are very rare.

SUBCLAVIAN ANEURYSM is nearly as frequent as carotid aneurysm.

ANEURYSM OF THE PERIPHERAL ARTERIES is mainly of surgical interest. It most commonly occurs in the common carotid, and is relatively frequent in women. It has been suggested that the carotid is likely to be strained or overstretched during parturition. Syphilis is found in all cases.

II. ANEURYSM OF THE ABDOMINAL AORTA AND ITS BRANCHES

Aneurysm may occur in any part of the abdominal aorta, but it is a comparatively rare disease. A forcible dynamic pulsation of the vessel is often mistaken for aneurysm, and no case should be diagnosed as aneurysm unless a tumour can be grasped between the fingers. Usually in true aneurysm there is evidence of syphilis and the Wassermann reaction is positive. A systolic thrill can sometimes be felt, and a systolic murmur is, as a rule, audible. The complications in abdominal aneurysm are many. Death may result from complete obliteration of the lumen by clots, by erosion of the vertebrae, and compression of the spinal cord, resulting in paraplegia. Occasionally the superior mesenteric artery may become blocked by a clot and acute intestinal obstruction result. The commonest complication is rupture, which generally takes place into the retro-peritoneal tissues, with the formation of a large rapidly-growing tumour in the flank. More rarely death takes place from rupture into the peritoneum or duodenum.

Treatment.—The treatment of abdominal aneurysm is the same as that of thoracic aneurysm. In cases where medical treatment is unsuccessful after a fair trial, surgical measures should be undertaken.

ANEURYSM OF THE SPLENIC ARTERY is occasionally met with. A tumour can be felt near the spleen and it may perforate into the colon. If the diagnosis can be made, removal of the aneurysm and of the spleen should be undertaken.

ANEURYSM OF THE MESENTERIC ARTERY generally results in plugging of the vessel or its branches, with the result that acute intestinal obstruction takes place and death occurs from this cause.

1030 DISEASES OF THE CIRCULATORY SYSTEM

ANEURYSM OF THE HEPATIC ARTERY is very rare.

ANEURYSM OF THE RENAL ARTERY has occasionally been noted, and in some cases successfully removed.

ANEURYSM OF THE FEMORAL ARTERY also occurs.

ANEURYSM OF THE POPLITEAL ARTERY is one of the most common of the peripheral aneurysms. It has been suggested that this is due to the fact of the exposure to stress and strain to which the popliteal region is subjected during violent lifting efforts.

In all cases of peripheral aneurysm a syphilitic basis must be investigated ; but the aneurysms of the muscular arteries of medium size are almost invariably due to medial degeneration, and a syphilitic aneurysm would be most unusual. Distal or peripheral ligature and excision have all been tried, but a great advance has recently been made in the treatment of aneurysm by Matas. After rendering the limb exsanguine, he freely opens the arterial sac and by a process of suturing reconstructs a channel between the afferent and efferent artery of the sac. He terms this procedure *Reconstructive Endoaneurysmorrhaphy*.

III. DISSECTING ANEURYSM

This may originate in an atheromatous ulcer. Very often the dissection of the coat is small, especially when the blood-pressure is not high. When, however, there is a very high blood-pressure and much degeneration of the media, an extensive dissecting aneurysm may occur. The degeneration of the media may cause a small split in the intima and the dissection separates the intima from the media, so that in some cases there may be a double tube instead of a single aorta. Extensive dissection frequently causes sudden death, but in other cases the patient may live on, and the association of a rapidly beating heart and a feeble pulse in the lower limbs has been suggested as a clinical sign by which the condition may be recognised. Turnbull has shown that in four out of five cases of extensive dissecting aneurysm of the aorta, due to medial degeneration, vascular hypertrophy was well marked, and consequently the blood-pressure was high during life. He also gives two examples of the rarer condition in which dilatation, rupture and dissecting aneurysm of the aorta are apparently due to congenital weakness, histological evidence of degeneration or inflammation being absent. ✓

IV. CIRROID ANEURYSM

Cirroid aneurysm is a condition in which an artery is dilated and tortuous. The affection is often due to medial degeneration of muscular arteries, particularly the splenic and temporal. This form is of little clinical importance. Less commonly it is due to defective development of the walls of arteries and their branches, and this form has been called serpentine angioma. The arteries, their branches, the capillaries, and even the efferent veins dilate progressively, causing destruction of the intervening soft tissues and erosion of bone. The superficial temporal, posterior auricular and occipital arteries are most commonly affected. It also occurs in the brain, pancreas, orbit, and the limbs. It is most common between puberty and 30 years of age.

Pathology.—The arteries are dilated, thinned and very tortuous, and the disease tends to spread towards the capillaries and also along the arteries which feed the aneurysm. The skin over the aneurysm is often atrophied and may become ulcerated, leading to very dangerous hæmorrhage.

Symptoms.—There is an ill-defined pulsating tumour on the scalp, in which the tortuous vessels may be felt. In rare cases the tumour may be slow in its growth, but this is generally rapid and the skin over it ulcerates, leading to hæmorrhage.

Treatment.—This is very difficult. In limited cases the tumour may be excised. Generally, however, ligature of the peripheral arteries of the growth is more satisfactory. Electrolysis and injections of perchloride of iron into the mass have been tried, with some success.

V. ARTERIO-VENOUS ANEURYSM

Arterio-venous aneurysm is the name given to the condition in which an artery and a vein communicate, and consists of two kinds—(1) aneurysmal varix, where the two vessels anastomose directly; and (2) varicose aneurysm, where the sac separates the connecting vessels.

(1) **ANEURYSMAL VARIX.**—The condition is usually traumatic in origin and generally occurs at the elbow, as the result of venesection. The artery wounded at the same time as the vein and they become connected, the result being that the vein becomes markedly dilated and tortuous.

The varix forms a soft, compressible, ill-defined tumour, which pulsates. Pain in the tumour is not uncommon. A marked thrill can often be felt and a loud bruit may be heard over the tumour. If the limb is raised the tumour shrinks, while it becomes large and congested if the limb is held downwards. The limb below the tumour is often œdematous.

In some cases the condition remains stationary, and all that is required is an elastic support. If, however, the aneurysm tends to increase in size, the artery should be ligatured above and below its communication with the vein.

An intrathoracic aneurysm may become adherent to a vein and perforate into it. The most common case occurs when an aneurysm of the ascending arch of the aorta perforates the superior vena cava. The latter vessel becomes greatly distended and an arterio-venous aneurysm is formed. There is often a sudden onset when the lumen of the two vessels becomes connected; there is distinct congestion of the head and neck and upper limbs, great distension of the veins, and often œdema. On auscultation over the tumour, a continuous humming murmur is heard, with marked accentuation during systole.

(2) **VARICOSE ANEURYSM.**—This occurs when an artery and vein are simultaneously wounded. A false aneurysmal sac is formed in the tissues and communicates both with the artery and vein. The symptoms are similar to those of an aneurysmal varix, but in addition there is a pulsating tumour, which can be distinguished from the dilated vein. This form of aneurysm should be excised by open operation.

ARTERIO-VENOUS ANEURYSM OF THE ORBIT OR PULSATING EXOPHTHALMOS.—This is a form of aneurysm by anastomosis, due to a communication having formed between the cavernous sinus and internal carotid artery as it passes through it. It is generally the result of a fracture of the base of the

1032 DISEASES OF THE CIRCULATORY SYSTEM

skull. The condition is usually unilateral, but may be bilateral, and the communication may take place immediately after the fracture, or evidence of the lesion may only appear days or weeks after the injury.

The main symptom is protrusion of the eyeball, the globe being displaced outwards and downwards. It may be seen to be visibly pulsating, but if not, slight pressure upon the globe of the eye will bring out pulsation. A loud bruit, either continuous or increased during systole, may be heard anywhere over the head; this roaring sound is generally very distressing to the patient. There is great dilatation of the veins around the eyelids, conjunctivæ and fundus. Headache is common.

The condition may last for years, and in a few cases spontaneous recovery has taken place.

The treatment of the condition is either compression or ligature of the carotid artery. The great danger in ligaturing the carotid artery is the occurrence of cerebral softening and hemiplegia. To avoid this, it is better to ligature the artery temporarily and see if any cerebral symptoms tend to develop; if they do, the ligature should be removed after 24 hours; but if they do not, the ligature may be tightened and the artery completely occluded.

DISEASES OF THE PULMONARY ARTERIES

The pulmonary artery is much less frequently the seat of disease than is the aorta, but it is liable to be affected by pathological changes of a similar character to those which are found in the systemic arteries.

Ætiology and Pathology.—Four main pathological changes are generally recognised, namely:

1. *Hypertrophy.*—This condition is associated with an increase in the blood-pressure in the lesser circulation and is found in cases of disease of the lungs, such as emphysema, pulmonary fibrosis and bronchiectasis, and also in disease of the heart, such as mitral stenosis. The intima of the pulmonary arteries hypertrophies and is prone to degeneration, so that patches of fatty change (atheroma) appear in the hypertrophied tissue. This form of intimal degeneration is superimposed upon hypertrophy, which is the result of obstruction to the lesser circulation and is independent of inflammatory change.

2. *Inflammation.*—There is no doubt that syphilitic inflammation may attack the pulmonary arteries as well as the aorta. The larger trunks may be affected by mesarteritis, and saccular aneurysms of the main branches have been described. Warthin has demonstrated the *Sp. pallida* in the wall of the pulmonary artery in a case of aneurysm of this vessel. The smaller arteries and arterioles in the lungs may also be affected by syphilitic arteritis, with endarteritis obliterans. The endarteritis, either by itself or in combination with thrombosis, may lead to complete occlusion of the lumen. Ayerza and his pupils have emphasised the importance of syphilis as an ætiological factor in the production of cyanosis and congestive heart failure in the absence of the usual causes of these conditions, such as emphysema and fibrosis of the lungs, or mitral stenosis. Fatty or calcareous changes may occur as secondary changes in the walls of the inflamed arteries.

Tuberculous inflammation of the pulmonary arteries is also common. Tuberculous endarteritis obliterans of small pulmonary arteries is frequent in phthisis. Tuberculosis of the lung or a bronchial gland may extend through the wall of a large artery to its intima, giving an intimal tubercle which when softened can lead to a general dissemination. The wall of a pulmonary artery exposed in a tuberculous cavity is frequently weakened by tuberculous or pyogenic invasion from without, and an aneurysm results. The profuse hæmoptysis found in the latter stages of chronic pulmonary tuberculosis results from the rupture of one of these aneurysms.

3. *Degeneration.*—Degeneration of the intima secondary to intimal hypertrophy or to inflammation has been described above. Slight primary intimal degeneration, or atheroma, is not uncommon in elderly subjects. C. F. Coombs and others have described cases of a severe atheroma of the pulmonary artery in young subjects, in whom there was no evidence of syphilis or of pulmonary or cardiac lesions. Coombs suggests that in these cases there is an inherited tendency to the intimal degeneration.

4. *Congenital malformations* of the pulmonary artery. In the majority of cases a stenosis is present, but in rare instances dilatation of the vessel has been found. These conditions are described under congenital heart disease (*q.v.* p. 955).

Symptoms.—The symptoms of the disease of the pulmonary artery are those of obstruction of the lesser circulation.

Dyspnœa is often an early symptom, and may occur on exertion or in nocturnal paroxysms. In the later stages it becomes constant, with attacks of orthopnœa. Cyanosis is one of the most characteristic manifestations, but it varies in intensity and also at the stage of the disease when it appears. Cyanosis is due to an imperfect oxygenation of the blood passing through the lungs at each cardiac cycle. It will, therefore, be most marked in those cases in which only a small proportion of the blood passes through the lungs at each beat, as in congenital pulmonary stenosis, or in which the capillary area in the lungs has been so reduced by emphysema or the lung itself has been so damaged by fibrosis that the circulating blood is imperfectly oxygenated. In mitral stenosis the degree of cyanosis is remarkably variable and probably depends as to whether secondary changes in the lungs have developed. In Ayerza's disease (syphilitic inflammation of the pulmonary arteries) the cyanosis may be extreme and the patients may have almost a black appearance (*cardiacos negros*). This may be due to the endarteritis obliterans of branches of the pulmonary artery, or to a coexisting syphilitic obliterating bronchitis, or a syphilitic pneumonia causing fibrosis of the lung.

Hæmoptysis may occur before cyanosis has become established or in the later stages. It may be slight or profuse, and may be associated with attacks of pulmonary artery thrombosis. Cough, with mucopurulent expectoration, is common, and attacks of vertigo may occur. Somnolence is not infrequently found when marked cyanosis is present. The fingers are not clubbed, except in cases resulting from bronchiectasis or fibroid lung.

The pulse is usually regular and the heart is much enlarged, especially the right ventricle. If mitral stenosis is present diastolic murmurs may be heard at the apex. There are no constant physical signs in the lungs, but if emphysema, fibrosis or bronchiectasis has been the determining factor, the physical signs characteristic of these conditions will be found. Œdema is

often present and may be extreme and the liver enlarged. The spleen is not palpable. The blood shows an increase in the number of red cells, up to 8,000,000, the number varying with the degree of cyanosis.

The radioscopic findings are characteristic. The right ventricle is enlarged, the pulmonary artery often dilated, and the branches of the pulmonary artery show more clearly than usual and can be followed into the lung and in some cases can be seen to pulsate. The electrocardiogram shows a marked right ventricular preponderance and alterations in the *P* wave, suggesting right auricular hypertrophy.

Diagnosis.—Cases of pulmonary artery affections secondary to pulmonary or cardiac disease can be distinguished by the presence of the symptoms and signs of the underlying lesion. There is no sure method of diagnosis between syphilitic and non-syphilitic cases. In syphilitic pulmonary arteritis the patients are usually between 30 and 50 years of age and may give a history of syphilitic infection. The Wassermann reaction in the blood is positive.

Course.—There may be a history of pulmonary symptoms, such as cough and dyspnoea, for many years. Later the intense cyanosis may develop, and this may last for 4 or 5 years. Some of these patients die in their sleep, but in others myocardial failure, with advanced anasarca, is the cause of death. Others die of complications, such as broncho-pneumonia.

Prognosis and Treatment.—The outlook depends on the causative factor. In early cases in which syphilis has been established as the cause of the inflammation of the pulmonary artery, anti-syphilitic treatment will retard the progress of the disease. In paroxysms of cyanosis, venesection gives marked relief. The usual treatment for congestive heart failure must be adopted, when this has supervened (see elsewhere).

PHLEBITIS

Phlebitis or inflammation of the veins may be sharply divided into two great classes—(1) non-suppurative or plastic phlebitis, and (2) the suppurative form. The terms endo- and peri-phlebitis have been used to indicate inflammation of the internal and external coats. Peri-phlebitis results from invasion of the veins by inflammatory processes outside it, or from injury. It may extend inwards towards the lumen of the vein, and result in endophlebitis and frequently clotting of the blood within the vein. Endophlebitis is usually the result of poisons or microbes circulating within the vein. Inflammatory changes occur in the endothelium, and a plastic inflammation results, and in consequence a clot or thrombus is set up within the vein. The clot may adhere to the vessel wall and completely obliterate it. Organisation of the clot by fibrous tissue may occur, the vein being transformed into a hard fibrous cord. In other cases the clot may become softened and broken down, and the circulation may be resumed through the vein. In certain cases changes in the composition of the blood may lead to clotting in a vein, and the presence of this clot itself may give rise to a plastic phlebitis; this is sometimes called *thrombo-phlebitis*. In other cases the vein and contained clot may become invaded by pyogenic organisms, and leucocytes will enter the clot and cause it to break down into a purulent fluid.

PLASTIC PHLEBITIS

Ætiology.—(1) Traumatic phlebitis; (2) the formation of a non-infective clot—thrombo-phlebitis; (3) gouty phlebitis may accompany an attack of gouty arthritis or may occur independently; (4) typhoid fever not infrequently causes phlebitis and thrombosis; (5) in pneumonia and influenza phlebitis is not an uncommon complication; (6) post-operative phlebitis is not at all uncommon in cases of operation on the lower abdomen and the bladder; and (7) puerperal phlebitis or phlegmasia alba dolens frequently follows parturition.

Phlebitis may attack any vein, but is most common in the lower limb, particularly in the saphena vein.

Symptoms.—Phlebitis is accompanied by pain and tenderness in the course of the affected vein. The vein can be felt as a hard cord. The skin may become reddened over the superficial veins, and the limb is often œdematous when thrombosis has taken place. There is usually more or less febrile disturbance. In gouty phlebitis, the pain is often severe, the areas of inflammation are often multiple; there is a great tendency for more than one vein to be attacked at once, and, in opposition to most forms of phlebitis, the disease may be symmetrical.

Complications and Sequelæ.—The complications and sequelæ of plastic phlebitis are those of the thrombosis which accompanies it, and will be described under thrombosis.

Prognosis.—This is always grave, unless treatment is very carefully carried out.

Treatment.—Patients with phlebitis should be put to bed, and the limbs elevated and wrapped in cotton wool. All sudden movement, friction or handling should be avoided. The bowels should be freely opened, as chronic constipation and stasis in the colon may impede the circulation in the iliac veins. In gouty phlebitis, the diet should be restricted to fish and light farinaceous foods, but when patients are marasmic and anæmic, the diet should be as liberal as the patient's digestive powers will permit. In all cases of phlebitis foods containing much lime-salts, such as milk, should be avoided. Potassium or sodium citrate with carbonate of ammonia and liquor ammonii acetatis are of service. Glycerine and belladonna smeared over the inflamed vein appears to ease the pain.

SUPPURATIVE PHLEBITIS

Ætiology.—Suppurative phlebitis is the result of infection of the walls of the veins with pyogenic organisms. The micrococci may be in the circulating blood, as in some cases of puerperal phlebitis, or they may reach the veins from a focus of suppuration around it, as in facial carbuncle, middle-ear disease, or inflammation of the portal veins—suppurative pyelophlebitis.

Pathology.—The coats of the vein are infiltrated with leucocytes, the clot which has formed within the vessel breaks down into yellow pus, and abscesses are not infrequently found along the course of the vein. Not uncommonly the septic inflammation spreads along a vein, splitting up the coats.

Symptoms.—There is a throbbing, smarting pain in the region of the

affected vein, and the part drained by the vein is œdematous. Not infrequently the septic process spreads along a vessel. There is often fever, a rapid pulse, a dry tongue, and delirium, and in many cases a succession of rigors indicates the development of pyæmia.

Complications and Sequelæ.—These depend upon the situation of the vein and the occurrence of emboli, owing to breaking away of the softened clot. (See Thrombosis.) When the vein is superficial the diagnosis is easy, but when a deeply-seated small vein is affected the only symptoms may be those of the pyæmia to which it gives rise.

Treatment.—The prevention of this disease by aseptic and antiseptic methods is one of the greatest advances in modern surgery. As soon as the disease is recognised, a ligature should be placed upon the vein between the affected area and the heart, the inflamed vein should be thoroughly laid open, the septic clot removed and the cavity thoroughly cleansed. In some cases where numerous abscesses are formed, amputation is the only means of arresting the general infection.

THEODORE THOMPSON.

THROMBOSIS AND EMBOLISM

Thrombosis is the name applied to the coagulation of blood within living vessels, whether in the heart, the veins or the arteries.

Embolism is the process whereby a portion of clot or other substance, such as parasites, fat globules, masses of bacteria or particles of tumour, is carried from one part of the circulation to another, and is impacted when it arrives at a vessel too narrow for its further progress. An infarct is the degenerated or necrosed condition of the tissues due to interference with the circulation of blood within it, and can be caused by embolism, thrombosis, endarteritis, endophlebitis, or strangulation of veins. An infarct is generally wedge-shaped in outline, with the base towards the periphery of the organ affected. As seen post mortem, it is either yellowish-white in colour (the white infarct), or blood-red in colour (the hæmorrhagic infarct).

In the case of the white infarct the tissue deprived of its blood supply becomes permeated with lymph from the surrounding living tissue, and coagulative changes take place in it. In the case of the kidney or spleen, the coagulable material is sufficient to render the infarct hard. In the case of the brain, less coagulable lymph is poured out, and the area of the brain affected becomes softened. In the early stages there is often a zone of congested vessels around a white infarct; this is a reaction on the part of the surrounding living tissues to the presence of the dead material. Later the infarct becomes invaded by fibrous tissue and a scar results.

In hæmorrhagic infarct, coagulation and necrosis also take place, but to this is added hæmorrhage, by diapedesis of the red blood cells from vessels of the collateral circulation. An hæmorrhagic infarct is commonly seen in the lung; a cone-shaped area of lung tissue becomes hard and dark red in colour. Should the embolus, instead of being aseptic, contain living micro-organisms, a septic process is set up within the infarct and an abscess results. Such purulent abscesses are commonly seen in the lungs, as the result of septic

phlebitis, and occasionally in the systemic system, as the result of septic endocarditis.

THROMBOSIS

Ætiology.—The causes of thrombosis are—(1) altered conditions of the blood or increase in its coagulability; (2) slowing of the current of the blood within the vessels; and (3) a lesion of the lining membranes of the vessel or cavity of the heart. Thus, thrombosis may occur in cases of chlorosis, where the blood is more coagulable than normal, in the appendages of the dilated auricles of the heart where the current of blood is feeble, and it may result from inflammation of the lining of the vessel or degenerative changes in its endothelium.

(1) **CARDIAC THROMBOSIS.**—Cardiac thrombosis is one of the commonest forms of thrombosis and is very important. It occurs in the left auricle, when it has become extremely dilated, as the result of mitral stenosis, or more rarely of mitral regurgitation. The ante-mortem clot generally begins to form in the dilated appendix of the left auricle, but it may extend by the deposition of excessive layers of fibrin and invade the auricle itself and a large ball thrombosis be formed within the cavity. Portions of the ante-mortem clot may break away from the thrombus, and may be carried into the left ventricle and into the general circulation, and embolism may occur in the brain, spleen, kidneys, intestines and the main arteries of the limbs.

Ante-mortem clot is occasionally deposited among the meshes and cavities of the dilated left ventricle. In cases of cardiac fibrosis and myelomalacia cordis, the result of disease of the coronary arteries, the lining of the heart may become affected and fibrinous deposits occur within the ventricle. Lastly, in septic endocarditis, large vegetations, consisting of clot and masses of micro-organisms, may occur. Inflammation of the ventricle and of the auricle may also be present, and ante-mortem clot may be deposited on these roughened surfaces. Portions of this clot may leave the ventricle and pass into the general arterial circulation, where the effect produced will depend upon whether the emboli are aseptic or contain micro-organisms.

Thrombosis in the right auricle occurs in many conditions where there is gradual cardiac failure and dilatation of the right side of the heart. Portions of ante-mortem clot form in the right auricular appendix, and parts may break away and pass into the lungs and an embolism of the pulmonary artery result. If the embolus is sufficiently large to cause blocking of the artery or of one of its main branches, sudden death ensues, but if only one of the smaller branches is affected, a pulmonary infarct results. Much more rarely ulcerative endocarditis occurs on the right side of the heart, and portions of the valves or affected clot reach the lungs in the same way.

Thrombosis of the coronary arteries is a very important condition, since it is a frequent cause of sudden death. The usual artery affected is the anterior interventricular branch of the coronary artery. Atheromatous plaques are constantly found within the thrombosed vessel, and sometimes atheroma has occluded the orifice of the artery. In cases where the circulation has been slowed and greatly diminished before the final clotting, changes in the wall of the left ventricle are very common. Syphilitic mesaortitis sometimes occludes the orifices of the coronary arteries.

(2) **VENOUS THROMBOSIS.**—*Thrombosis of the lateral sinus occurs in*

disease of the middle ear. The mastoid cells become infected with pyogenic organisms and the disease spreads to the petrosal or sigmoid sinus. The clot in the vein becomes softened by pyogenic organisms, and particles break away and are conveyed to the lungs, in which pyogenic abscesses are formed.

The symptoms of septic thrombosis of the lateral sinus—and its continuation of the jugular vein—are infiltration of the tissues of the neck, with a cord-like induration of the vein itself, with some restriction of the movements of the head. There is a history of a chronic and often offensive discharge from the ear of the same side. A high temperature and rigors, due to flooding of the circulation by poison, occur when a portion of the septic clot is dislodged. In these circumstances the jugular vein should at once be ligatured below the clot, in order to prevent further portions of the clot gaining access to the blood stream. A radical mastoid operation should also be performed, the sinus opened and its septic contents removed.

Thrombosis of the longitudinal sinus of the brain occurs as the result of injuries and infected wounds of the skull. It is a common war injury, the vertex of the head having been injured by a bullet as the soldier passes along the trench. Thrombosis of the cranial sinuses also occurs in marasmic patients, but it is usually agonal.

In many of these cases, owing to the vertical position of the leg areas in the brain, a paraplegia is produced, while the arms are not affected. The condition should be treated by trephining and draining the cranial cavity. Occasionally the longitudinal sinus becomes thrombosed in septic conditions in children and also in chlorotic anæmia in adults.

Thrombosis of the cavernous sinus is not infrequently the result of the extension of a chronic suppurative process of the sphenoidal cells at the back of the nose. The cavernous sinus is also affected by septic processes on the face; a small boil on the nose or a mosquito sting on the face may produce a septic thrombosis of the angular vein; this vein communicates with the ophthalmic vein, and the septic clot may extend along the latter into the cavernous sinus. As the venous plexuses of the pterygoid and zygomatic fossæ communicate through the foramina in the middle fossa and by the inferior ophthalmic vein, purulent inflammation of the jaw and of the teeth sockets is sometimes a cause of cavernous thrombosis. The result is that a marked degree of exophthalmos and swelling of the lids, and œdema of the optic disc and extensive retinal hæmorrhages occur. Not infrequently the septic condition of one cavernous sinus spreads to that on the other side through the circular sinus, and the exophthalmos may be double. Death from pyæmia or meningitis results. Owing to the position of the sinus, operation is impossible.

Femoral thrombosis is perhaps the commonest form of thrombosis. It frequently occurs after parturition and in anæmic and marasmic states. It is met with after infectious fevers, especially after typhoid fever, more rarely after influenza and pneumonia. It also follows operations, especially if a septic condition has been dealt with, or results from the operation. The thrombosis generally occurs in the femoral vein, and there is often some rise of temperature and a slight rise in pulse-rate. The limb affected becomes œdematous, and a hard cord is found in the course of the vein.

In other cases thrombosis of the veins may also occur in marasmic conditions secondary to carcinoma, tuberculosis and tertiary syphilis.

Complications and Sequelæ.—Collateral circulation is usually satisfactorily accomplished in femoral thrombosis. In cases where the arteries as well as the veins are involved gangrene may occur. Occasionally the thrombosis may spread up into the iliac vein and into the inferior vena cava, in which case both legs may become swollen and œdematous. Even in cases where the inferior vena cava has become thrombosed, recovery may take place, collateral circulation being established by means of veins passing up from the legs into the axillæ. If, however, the clot reaches the entrance to the renal veins, death nearly always results from renal thrombosis. Embolism is not at all uncommon in femoral thrombosis, the clot passing into the right auricle, and then into the right ventricle and pulmonary artery.

Treatment.—Complete rest for 4 or 5 weeks, as a precaution against embolism, should be insisted upon. Avoidance of foods containing quantities of lime salts, such as milk, and the administration of citrates and salts of ammonia will materially help in the treatment of the case. The leg should be elevated and wrapped in cotton wool and kept warm.

Thrombosis of the portal vein is not uncommonly the result of septic conditions within the abdomen. The most common affection is suppuration in the region of the appendix. The condition is not always acute. Gastric and duodenal ulcers also lead to portal thrombosis, and tubercular glands along the course of the portal vein have been found to cause clotting within the lumen of the vessel. Dysenteric ulcers resulting from bacillary dysentery may also give rise to septic portal thrombosis, but typhoid ulceration very rarely does so.

The effect of portal thrombosis is to produce a portal pyæmia, portions of the clot passing into the liver and causing abscesses within the radicles of that organ. Occasionally the portal vein itself becomes converted into a sac containing pus, and the liver is then riddled with abscesses along the course of the portal branches. This condition is known as *portal pyelephlebitis*.

Symptoms.—The symptoms of septic portal thrombosis are the occurrence of fever and of rigors. The liver becomes enlarged and tender, and jaundice of a slight degree is quite common.

As the condition is such a generalised one, recovery very seldom takes place, even if treatment is adopted.

Treatment.—This consists in removing the cause and incising any liver abscesses.

(3) **ARTERIAL THROMBOSIS.**—Arterial thrombosis is much rarer than venous thrombosis. It is generally due to arterial embolism, but is occasionally the result of trauma or disease of the arterial walls, such as atheroma or endarteritis.

Thrombosis of the coronary arteries of the heart has already been described (pp. 974–977). Thrombosis is very common in the small cerebral arteries, especially when they have become narrowed as the result of disease. In middle-aged people this narrowing is usually the result of syphilitic endarteritis, while in the elderly the arterial lumen is diminished by atheromatous changes in the wall of the vessel.

Thrombosis of the main artery of a limb usually results in gangrene; the limb becomes first white and pallid, later mottled in appearance, and finally black. If the patient survives the immediate shock and the disease

to which the thrombus owes its origin, a line of demarcation will form between the vital and devitalised tissues, and the limb should be amputated well above this level.

EMBOLISM

Embolism may occur in three main situations, namely—(1) In the systemic circulation; (2) in the pulmonary circulation; and (3) in the portal circulation.

Emboli in the systemic circulation are derived from ante-mortem clots in the left auricle and left ventricle. These clots are formed in cases of mitral stenosis and more rarely in mitral regurgitation, and also when the left ventricle is greatly dilated and hypertrophied. In these cases the emboli are aseptic. Systemic emboli also occur in septic endocarditis, when portions of the valve break away or masses of fibrin and micro-organisms pass into the general circulation. These emboli are septic, and when they reach their destination usually form abscesses.

Emboli in the pulmonary circulation usually have their origin in clots which form within the right auricle and right ventricle. More rarely they are the result of septic endocarditis of the tricuspid and pulmonary valves. They may also come from any part of the systemic venous system. A very important form of pulmonary embolism is met with after abdominal operations and after childbirth. About the tenth day after an apparently successful abdominal operation or an uneventful parturition, a pulmonary embolism may occur with appalling suddenness. Death may take place at once, or hæmoptysis and pleurisy supervene. The clot forms in the common iliac vein, at the junction of the internal and external iliacs. Not only may a clot pass along the veins, but we also get droplets of fat in fat embolism, air bubbles in air embolism, and masses of parasites in parasitic embolism.

In embolism in the portal circulation portions of clot in the radicles of the portal vein are finally arrested in the liver.

Symptoms.—1. *Embolism of the cerebral arteries.*—The onset is sudden, and the left side of the brain is rather more often affected than the right. Hemiplegia or aphasia is produced; consciousness is only lost for a few minutes during the attacks.

2. *Embolism of the splenic artery.*—The onset is sudden, with pain in the left side and sudden enlargement of the spleen, which is very tender. During the next few days, the spleen diminishes in size, but it often remains permanently enlarged.

3. *Embolism of the renal arteries.*—Sudden pain in the back is produced, and blood and a little albumin are present in the urine. The hæmaturia may last for a week or 10 days and then disappear.

4. *Embolism of the superior mesenteric artery.*—The patient is seized with sudden, violent abdominal pain and distension. The collateral circulation, in spite of the numerous vascular arteries that supply the intestine, fails, and gangrene of the small intestine results. There is a complete intestinal obstruction, and blood finds its way into the stools and into the peritoneal cavity. Operation should be at once undertaken, but owing to the large amount of bowel affected recovery is very rare.

5. *Embolism of the central artery of the retina.*—This is not an uncommon event in cases of mitral stenosis and in septic endocarditis of the aortic

and mitral valves. The patient is seized with pain in the eye and becomes suddenly blind on one side. The optic disk becomes pale and the retinal vessels small. Occasionally only a single branch of the vessel is affected.

6. *Embolism of a large artery in a limb.*—This sometimes occurs. There is acute pain in the limb, followed by numbness and loss of power. The pulse is imperceptible below the seat of the embolism, and gangrene results.

7. *Air embolism.*—Air may enter the veins during operation on a large vein, or during intravenous injection of saline or other solutions, or after distension of the bladder and the urethra with air. It is said that occasionally air may enter the open uterine sinuses after parturition or miscarriages, but some of the cases are probably due to the invasion of the *Bacillus aerogenes capsulatus*. Air embolism is undoubtedly capable of causing death, but a small quantity may enter a vein without any effect whatever, or if some disturbance should arise without fatal termination. The exact way in which air embolism causes death is doubtful; it may be due to arrest of the pulmonary circulation or to cerebral anæmia.

The diagnosis is not difficult, the respiratory embarrassment, convulsions, the feeble pulse and the characteristic sound upon air entry into the veins are usually sufficient.

Treatment consists in immediately occluding the vein into which the air has entered. Stimulants should be administered hypodermically and nitrite of amyl inhaled. Venesection may be used to relieve the embarrassment of the heart.

8. *Fat embolism.*—Fat may reach the blood vessels in cases of fracture of bones and in cases of hæmorrhage into or rupture of the liver. The fracture is usually situated in the long bones, generally in the tibia or femur, and occasionally in the ribs. Fat embolism may occur within a few hours of fracture of the bones.

The fat droplets first lodge in the capillaries of the lungs. Occasionally they are forced on through the lungs into the general circulation, and the glomeruli of the kidney may be plugged with fat cells, and they may also lodge in the brain or spinal cord.

The patient becomes cyanosed, and crepitations from œdema of the lungs may be heard at the bases. The temperature remains normal. Cerebral complications, such as delirium, coma and rarely localised paralysis, may be found. The urine should always be examined, as oil drops have been detected by staining with osmic acid, and also the retina, as in one case the fat drops were recognised in the retinal vessels before death.

When fat embolism occurs within a few hours of fracture of the bones, it has to be diagnosed from the general shock of the accident. It is doubtful whether fat embolism in the lungs can alone cause death. It is probable that a fatal termination is due to the disturbance of the kidneys or lesions of the brain.

The indication for treatment is to sustain and stimulate the heart. Nitrite of amyl is often useful, and inhalations of oxygen should be given to lessen cyanosis.

9. *Paradoxical Embolism.*—In certain cases of venous thrombosis, emboli occur not only in the lungs but also in the systemic arteries. It has been shown that in these cases the embolus has passed from the right auricle to the left auricle through a patent foramen ovale. These crossed or para-

doxical emboli in many cases are preceded by pulmonary embolism. The latter causes a rise in pressure in the right auricle and a fall in pressure in the left auricle, and thus the embolus in the right auricle can pass to the left side of the heart.

THEODORE THOMPSON.

ARTERIAL BLOOD-PRESSURE

By the blood-pressure is meant the pressure that the blood exerts against the wall of the vessel in which it is contained. The term, therefore, includes endocardial pressure, arterial pressure, capillary pressure and venous blood-pressure. We are here concerned only with arterial blood-pressure. This depends upon (1) the force of the contraction of the left ventricle; (2) the volume of blood which the left ventricle propels into the already full arteries; (3) the elasticity of the middle coats of the large arteries; and (4) the peripheral resistance.

The arterial pressure synchronous with the systole of the ventricle is called the *systolic blood-pressure*, that synchronous with the diastole is called the *diastolic blood-pressure*, while the difference between the two is called the *pulse-pressure*. The *mean arterial pressure* is the mathematical mean between the systolic and diastolic pressures.

The introduction of the sphygmomanometer has proved of great value in clinical medicine. The results obtained are more reliable, and, indeed, not infrequently the practitioner will detect cases of hypertension which might otherwise have been overlooked; the detection of this condition in its earliest stages is of great practical importance, because it is in these stages that therapeutic measures are most likely to be successful; and the practitioner is enabled to compare the blood-pressure readings while patients are undergoing treatment either for hypertension or hypotension. A word of warning, however, is necessary: it should be remembered that the sphygmomanometer may exhibit fallacies and possesses limitations, and there is undoubtedly a danger of overestimating its value in clinical work, when we rely upon its readings alone as an indication of the patient's condition. Blood-pressure measurements should be considered in conjunction with other clinical data. Variations in blood-pressure occur under physiological conditions. Moreover, in all probability the normal blood-pressure has a wider range of variation in different individuals than is generally supposed, and, if this be so, great caution should be exercised in arriving at the conclusion that a blood-pressure outside what is generally supposed to be the normal limit is necessarily indicative of a diseased state. In considering the question whether a rather high pressure reading is normal to the individual, or is indicative of a pathological departure, it is important that inquiries should be made with regard to four points—viz. (1) what was the patient's usual blood-pressure previously? (2) are there any symptoms other than a supposed abnormal blood-pressure, such as a sensation of fullness or throbbing in the head? (3) what is the condition of the heart, the arteries, and the kidneys? and (4) what is the result of treatment? If there be a fall in the

pressure readings, together with a coincident improvement in the general health of the individual during treatment, it may be inferred that the higher pressure reading is pathological.

HYPOTENSION

In pathological hypotension the blood-pressure is persistently below the normal for the individual.

Ætiology and Pathology.—Hypotension may be met with in Addison's disease, in acute cardiac disease, especially coronary disease, in some cases of chronic valvular disease, particularly mitral disease, in most cases of fatty degeneration of the myocardium, in some cases of fibrosis of the myocardium, in congenital deficiency of the vasomotor system, in focal sepsis, in acute infective diseases, especially enteric fever, influenza and diphtheria, in pulmonary tuberculosis, in shock and collapse, in the early stages of Graves' disease, in carcinoma and other wasting diseases, in cerebral thrombosis, and in neurasthenia.

The chief factors in the causation of subnormal arterial pressure are (1) a diminution of the ventricular output, and (2) lowering of the vasomotor tone, splanchnic stasis being usually associated with the latter. It should be noted that hypotension is more often an indication of derangement of the vasomotor system than of cardiac impairment. Some are of opinion that in hypotension due to lowering of the vasomotor tone, there is in the large majority of cases adrenal insufficiency, frequently thyroid insufficiency, and not rarely pituitary insufficiency, and that these are the cause of the condition; and, therefore, that in all cases of this group an endeavour should be made to ascertain whether there is endocrine insufficiency, and if so to what extent, with a view of remedying this, in the belief that when once this is done the arterial pressure will be raised to normal and remain so, as long as these glands continue to functionate effectively. Adrenal insufficiency may be due to, among other things, inadequate development, lesions of the adrenals, and focal sepsis.

Symptoms.—Among these are asthenia—especially premature exhaustion on maintaining the upright posture, giddiness and faintness—especially on change of posture, neurasthenia, mental depression, insomnia, irritability of temper, nervous instability, sensitiveness to cold, numbness, and pallor or lividity of the extremities, subnormal temperature, increase in the cardiac rate of more than 10 per minute when the individual assumes the upright posture after lying down, and splanchnic stasis. When giddiness and faintness are especially associated with change of posture, it is suggestive of vasomotor derangement, as is also an abnormal increase in the pulse-rate on assuming the upright posture after lying down. In splanchnic stasis, pressure on the abdomen by the hand while the patient is lying down is sometimes accompanied by distension of the jugular veins.

Treatment.—The ætiology, including for focal sepsis, should be reviewed, with the object of treating the underlying cause. In acute cases rest in bed may be advisable; and after the acute stage has passed, great care should be taken to avoid over-exertion, and an adequate amount of rest after exertion, and before and after meals, is indicated. In shock and collapse the patient should lie on his back, and the foot of the bed may with advantage

1044 DISEASES OF THE CIRCULATORY SYSTEM

be raised by 1 or 2 feet. Massage is helpful in certain cases. A tepid or cold sponge bath in the morning, followed by suitable exercises, and residence in a bracing climate are to be commended. The proportion of those articles of food which especially stimulate the cardio-vascular system, such as meat and meat-extractives, should be increased, roasted meat being of greater value than meat which has been boiled, while meat soups and gravies should also be given. Cod-liver oil, malt, glycerophosphates, phosphorus, iron, and arsenic may be tried. Digitalis, and to a less extent strophanthus, have gained a reputation in the treatment of hypotension; but my investigations have shown that, *judged by the methods in use for observing the blood-pressure clinically*, the internal administration of digitalis does not raise the blood-pressure in man. Strychnine also has a considerable reputation in the treatment of this condition, especially when present in diphtheria or other acute infective diseases. Among other remedies advocated are ephedrine, adrenaline, pituitary extract, and ergot. The wearing of an abdominal belt is very useful in some cases of hypotension.

HYPERTENSION

In pathological hypertension the blood-pressure is persistently above the normal of the individual; *temporary* supernormal blood-pressure is found, for example, in the nervous excitement incidental to medical examination. The late Sir Clifford Allbutt introduced the term *hyperpiesia* to denote a clinical condition in which there is a persistently-raised blood-pressure independent of renal disease. Some writers use the term *essential* hypertension.

In the course of time arterial hypertrophy and cardiac hypertrophy, more especially of the left ventricle, tend to develop; and still later fatty degeneration in the hypertrophied tissue of the arteries, resulting in a weakening of the walls of the vessels, and it may be ischæmic fibrosis of the organs may occur. These morbid changes are fully described on pages 1016, 1017. Hypertension is also often a factor in the causation of atheroma.

Symptoms.—The patient is often plethoric and well nourished. There may be a complete absence of subjective symptoms for some years. The patient is, however, apt to suffer from a sensation of fullness and throbbing in the head, headache, usually in the occipital region, flushings, tinnitus aurium, flashes of light before the eyes, giddiness, insomnia and palpitation. The systolic blood-pressure in cases of simple hyperpiesia varies from 170 to 200 mm.; in cases associated with chronic interstitial nephritis it may reach even 300 mm. or more; and in secondary contracted kidney and in polycystic disease of the kidneys it varies between 160 and 220 mm. There is evidence of high-tension pulse. The vessel wall may be felt to be uniformly thickened—the so-called “whip-cord” artery. As the muscular arteries are those chiefly affected, the radial, the brachial and the temporal arteries are frequently found to be involved. There may be the physical signs of hypertrophy of the left ventricle, reduplication of the second sound over the septum ventriculorum and accentuation of the aortic second sound. Later on the history may show great diversity. This is fully dealt with in *The Heart in Hypertension* (see pages 960–962) and *Arterial Hypertrophy* (see pages 1015–1018).

Diagnosis.—In cases of hypertension and cardio-vascular hypertrophy

it is necessary to distinguish between hyperpiesia and chronic interstitial nephritis, in which connection the following are among the points which should be noted. In hyperpiesia the patient is often plethoric, with a high colour and well-nourished body, there is absence of symptoms of toxæmia, and the urine is of good colour and of normal specific gravity—indeed, it differs from healthy urine only in the presence of a trace of albumin and occasional casts of granular or hyaline kind; while in chronic interstitial nephritis there is often a sallow tinge in the complexion and loss of weight, gastric disturbance is more often that of hypochlorhydria than is the dyspepsia of hyperpiesia, and the urine is of low specific gravity. Further points in the differential diagnosis of hyperpiesia will be found on pages 1017, 1018.

Prognosis.—This is dealt with on pages 962 and 1018.

Treatment.—Firstly, it is exceedingly important thoroughly to review the ætiology of the condition, including a searching inquiry for focal sepsis—from the teeth (including X-Rays examination), the tonsils, the accessory nasal sinuses, the colon, and the genito-urinary tract—and the underlying cause should be adequately treated.

Secondly a detailed investigation of the patient's occupation, including hours of work, his general mode of life, hobbies, how long he takes off for his meals, his hours in bed, the amount and character of sleep, his habits and his mental character, should be made; and anything harmful should be corrected.

In the next place, hypertension is an excellent example of the value of treating not only the disease, but the patient. He should be reassured and encouraged. It is inadvisable to let him know the exact blood-pressure readings.

It is very necessary for the patient to live within the limits of his diminished cardio-vascular strength. He should be in bed for at least nine hours each night; and take at least an hour, and preferably longer, off for lunch, and a rest after finishing eating. A day in bed each week may prove very beneficial. The amount of physical, and mental, effort should stop short of inducing any abnormal, subjective symptoms, or rise in blood-pressure. Suitable and regulated exercise may be helpful. Walking is an excellent form; while riding a non-pulling horse, quiet cycling, golf, Swedish exercises and massage may prove to be suitable in certain cases. All excitement, worry and other forms of emotional stress and strain should be carefully avoided. There should be an adequate amount of variety in his life and of holidays. Stooling, straining at stool, and cold and hot baths are contra-indicated; but a warm bath, the temperature of which is gradually lowered, may be taken daily.

If the patient suffers from an unduly excitable nervous system, or is prone to worry or be anxious, sedatives are exceedingly useful (see page 833). Among the best of these is luminal, commencing with $\frac{1}{4}$ — $\frac{1}{2}$ grain four or three times daily, and gradually reducing to the minimal daily dose, which may be increased at any time if and as required.

If at any time there is tiredness or exhaustion, a sufficient period of rest, both physical and mental, is indicated.

The amount of fluid with meals should be diminished, while an ample quantity should be taken between meals. Some prefer the mildly alkaline waters. An excessive amount of food should be avoided—indeed, the amount should preferably be rather less than is needed. With regard to the character

of the food, some writers lay great emphasis on the necessity for drastic regulations. I personally do not agree with this. On the other hand, I am of opinion, however, that a regulated diet of moderate latitude may be of great value. Those articles of food which especially stimulate the cardiovascular system should be reduced and proportionately to the degree of hypertension. The quantity of beef and mutton should be diminished. Meat which has been boiled and is taken without the gravy is preferable to roasted meat taken with the gravy. Meat extractives, such as meat soups and gravies, liver, kidneys, sweetbreads and brains are better avoided altogether. Some physicians attach great importance to the diminution or exclusion of chlorides from the diet. If this view be correct, it should be noted that the deprivation of the salt usually added at table is not enough; food-stuffs which, before being cooked, have the smallest proportion of salt should, therefore, be chosen. Chloride of potassium may be taken in place of chloride of sodium as a table-salt, but some find it disagreeable to the taste. An exclusive diet of suitable fresh fruit, or of milk, or of both, on one day a week or more frequently may be helpful. Moderation in the use of tobacco, tea, and especially coffee should be enjoined. Alcohol is better avoided altogether, but if the hypertension be not considerable, a moderate amount may be allowed, preferably in the form of well-diluted whisky, or light wines, and only with meals.

Purgatives are useful in the treatment of hypertension, and it should be noted that a slight laxative action of the bowels each day is of greater value than an occasional purge. In choosing an aperient, saline purgatives, as they induce fluid motions, are the most suitable, and should be administered in hot water some time before breakfast. It is advisable also to administer some mercurial preparation once a week at bedtime. The functions of the skin should be attended to, and in this connexion a warm equable climate and woollen underclothing, especially in winter, are to be commended.

Periodic courses of nitrites, or of potassium iodide (grs. 5-20), or alternating them, may be tried. My experience, however, has been disappointing, but sometimes they are beneficial in moderate hyperpiesia. If nitrites be used, those whose action is slowest and most prolonged are preferable, and, therefore, mannitol nitrate, erythrol nitras, sodium nitrite and nitroglycerine, in the order named. They may be administered in increasing dosage until the physiological effects are obtained, while they may be continued in rather smaller doses for considerable periods in suitable cases. Some authorities believe that the hippurates and benzoates are useful. Recently glandular extracts, especially thyroid and ovarian, and liver extract have been tried, but I am very doubtful about the last named.

Hydrotherapy may be of service. A Turkish bath once or twice a week, perhaps followed by massage, or hot packs about thrice weekly, may be of service in suitable cases. A regular course of balneological treatment is sometimes beneficial, and different kinds of baths, among these being the Aix-les-Bains douche, are used.

Diathermy, high frequency currents and other forms of physiotherapy have recently been employed.

Venesection may be very valuable when the blood-pressure is very much raised, particularly if there are any head symptoms, or there are indications of great distension of the chambers of the right side of the heart. At least

a pint should be withdrawn. This method of treatment may be repeated at intervals.

If the foregoing measures fail, a long holiday is sometimes useful.

If there should be a dangerous rise in the blood-pressure, or a cardiac or cerebral attack should threaten, complete rest in bed, starvation and, it may be, venesection are indicated.

For the treatment of cardiac failure in hypertension, see page 962.

FREDERICK W. PRICE.

SECTION XIV

VASOMOTOR NEUROSES (ANGIO-NEUROSES)

INTRODUCTION

UNDER this heading are described several diseases in which vasomotor disturbance is the prominent symptom. Sensory, secretory and trophic disturbances may also be present. These diseases differ from each other both in regard to the nature and location of the vasomotor changes. Thus in Raynaud's disease there is a spasm of peripheral arteries. In erythromelalgia there is vaso-constrictor paralysis or excitation of the vaso dilator nerves. In angio-neurotic oedema there is disturbance of capillary permeability, and perhaps of capillary tone. These diseases are described as vasomotor neuroses because a lesion of structure is not an essential part of their pathology, and because a considerable functional element is generally present. Thus they are common in persons who have an unstable nervous temperament, and emotional disturbance and fatigue play a not unimportant part in their ætiology. It has been thought in the past that these diseases were primarily due to disorder of the involuntary or vegetative nervous system. Lewis, however, has shown in the case of Raynaud's disease that a local fault of the vessels rather than a disordered vasomotor impulse determines the spasm of the digital vessels, and he finds the explanation of Raynaud's disease in terms of vasomotor dysfunction unconvincing. Too little is known of the ætiology of acroparæsthesia, erythromelalgia and Milroy's disease to throw light on this matter, but whatever the basic pathogeny of these conditions may be, vaso-dilatation is a prominent feature of erythromelalgia.

A hard and fast distinction cannot be drawn between these diseases occurring as neuroses and similar syndromes complicating recognised pathological states, such as lesions of the spinal cord or brain (tabes dorsalis or hemiplegia), lesions of peripheral nerves (peripheral neuritis), and lesions of vascular channels, or local pressure effects, such as may result from a cervical rib. Nor are they separated by a rigid line from slighter manifestations of vasomotor instability, such as are frequent in women at the climacteric, and in clinical disorders resembling exophthalmic goitre. They are undoubtedly akin to such common symptoms as flushings, cerebral hyperæmia, facial congestion, angio-spasm in all its varieties, tachycardia (in some of its forms), anginal attacks, migraine, vertigo, tinnitus aurium, universal or circumscribed hyperidrosis, and gastric disorders of certain forms of functional gastric dyspepsia.

Lewis's studies on the local vascular reaction to irritation of the human skin, have thrown much light on these diseases. He showed that there are three components in the reaction: (1) a primary dilatation of capillaries—the *red line*; (2) an increased permeability of these capillaries, producing the *wheel*,

which is independent of the nerve supply ; and (3) the *flare*, which depends on the integrity of the sensory nerve fibres in the neighbourhood. All these phenomena can be produced by an intradermal injection of histamine, and he attributed them to the liberation of this or some similar chemical substance to which he gave the name of "H-substance." It has been suggested that local liberation of histamine may play a part in producing the vesicles in herpes and the rash in erythema nodosum, as well as some of the phenomena of the angio-neuroses. It is of special interest that these reactions are partially dependent upon and partially independent of the nervous system. Dale's observation that adrenaline directly antagonises histamine explains its usefulness in the treatment of angio-neurotic oedema.

RAYNAUD'S DISEASE

Synonym.—Symmetrical Gangrene.

Definition.—A paroxysmal affection of the blood vessels of the extremities, frequently symmetrical, characterised by persistent ischæmia or a passive hyperæmia, which leads to disturbance of function, or to a loss of vitality with necrosis.

Ætiology.—The cause of Raynaud's disease is unknown. It is more common in women than men. It occurs at any age, though most common in the second and third decades. The disease is to some extent constitutional. Thus it may occur in more than one member of a family. In other cases it may be associated with hysteria, epilepsy and neurosis. Congenital narrowness of the aorta (Oppenheim), exhaustion and anæmia are said to be predisposing causes. It sometimes complicates diseases of the spinal cord, namely, tabes dorsalis, syringomyelia, disseminate sclerosis and tumours. A few cases are due to syphilis, congenital or acquired, as was first suggested by Hutchinson. It has occasionally been observed after acute infections, and cases due to malaria have been reported. Intestinal toxæmia may be an ætiological factor. Lead and tobacco are possible causes. The importance of tobacco in thrombo-angiitis obliterans, intermittent claudication and some forms of anginal pain is of interest in this connection. Exposure to cold commonly determines an attack.

Pathology.—Lewis has shown that the basis of Raynaud's disease in certain cases in which the fingers were affected depends on an abnormality of the digital arteries, which shows itself in a hypersensitiveness of these vessels to relatively low temperatures. It seems, according to his observations, that the fault lies primarily in the vessel wall rather than in the nerve supply to the muscle fibres. In advanced cases there is endarteritis, and there may be complete occlusion of the lumen of the artery. Peripheral nerve changes have been described and are probably secondary. When due to syphilis or disease of the nervous system, the pathology is that of the primary disease.

Symptoms.—The affection is characteristically paroxysmal. The attack begins in the fingers or toes, with numbness and tingling, or pain. The pain is most severe in the distal part of the limb. It gradually increases and may become intense. The attack may be preceded by pain in the whole extremity. At first the affected parts are congested and cyanosed, or they may be white and cold like dead fingers (*local syncope*) ; the vessels in this stage are con-

tracted, so that no blood enters the part. After an interval of perhaps an hour or two, the fingers or toes become red and hot (*active hyperæmia*); the vessels dilate widely in this stage. More commonly there is an intervening period of *local asphyxia*, during which the affected part is deeply cyanosed—blue or blue-black—a condition which may persist, with variations, for days, weeks or months. It may be accompanied by swelling of the part. The process gradually subsides, or is followed by the stage of hyperæmia, and recovery occurs. Alternatively, gangrene develops, with the appearance of small black spots or vesicles filled with bloody fluid. These burst and a black scab forms, which gradually separates, leaving a scar, or an ulcer that heals slowly. In this way the pad of a finger may necrose, or the necrosis may involve the tip of the finger, the terminal phalanx, or the whole finger. More than one finger or toe may be lost in very severe cases. A line of demarcation gradually forms and the necrotic part separates. Movements of the affected part are stiff and slow, and their sensibility for all kinds of sensation is greatly diminished. In some cases the edges of the ears, the tip of the nose, the chin, the lips and the eyelids are affected.

As in other conditions associated with impaired capillary circulation, the reaction of the skin to the local application of histamine, which has already been described, is delayed and reduced.

Mental depression accompanies a moderate or severe form of Raynaud's disease, and gastric disturbance; for example, anorexia and vomiting may precede or accompany an attack. Osler reported a case complicated by three attacks of aphasia with hemiplegia, ending in recovery. There may be affections of the special senses (hemipopia, deafness, tinnitus and affections of the sense of taste), and albuminuria, glycosuria and hæmoglobinuria have been observed. An associated multiple arthritis is sometimes seen. The chronic form may progress to scleroderma; occasionally true generalised scleroderma begins with features of Raynaud's disease.

A severe attack lasts from 2 to 4 months or even longer. There may be no further attack, or there may be a recurrence after an interval of a year or more.

Mild degrees of Raynaud's disease scarcely merit the title, and are relatively common. Only a part of a finger, or one finger, or the fingers alone, or the hand as far as the wrist (often also the toes), go numb and white in winter or when bathing, and with a warmer temperature there returns the stage of active hyperæmia—the so-called "beef-steak" hand. The circulation may return to normal without a marked stage of hyperæmia. Chilblains belong to this group of vasomotor manifestations, and severe chilblains may lead to superficial necrosis. Transition forms between erythromelalgia and Raynaud's disease have been described.

Diagnosis.—Raynaud's disease differs from frost-bite in that the sequence of events in the former is usually syncope, cyanosis, hyperæmia, while in the latter it is hyperæmia, cyanosis, syncope. In mild and more chronic forms of the disease, the differential diagnosis from acroparæsthesia may arise. The age of onset is different. In general, acroparæsthesia is a subjective complaint. The feeling of numbness and tingling is continuous, and sometimes painful, and in rare cases there is evident pallor of the fingertips, but asphyxia and necrosis do not occur. The toes are rarely affected. Local gangrene of the toes occurs in senile and diabetic arterial disease. In

both conditions arterial disease is a marked feature, and the pulse in the dorsalis pedis artery is generally absent; the latter condition is obvious in the accompanying glycosuria. The differential diagnosis from thrombo-angiitis obliterans is more difficult, since it occurs in the age period in which Raynaud's disease is most common, and in its early stages may closely resemble Raynaud's disease. Thrombo-angiitis is not paroxysmal. It is most common in male Jews of Polish extraction; excessive cigarette smoking is thought to be a factor. Its distribution tends to be asymmetrical, and there is obliterative endarteritis and thrombosis of the vessels. As Osler remarked, necrosis in Raynaud's disease is a simple matter, as simple as if a string were tied tightly round a finger-tip. To this extent the possibility of self-mutilation requires mention. Leprosy is recognised by its specific characteristics. Erythromelalgia is not paroxysmal, is accompanied by swelling, does not involve local syncope, does not proceed to gangrene, and is aggravated by dependence of the part affected and by warmth.

Prognosis.—The prognosis to life is good. In rare cases septic infection may cause death. Severe attacks are resistant to treatment. Relapses are common, but the attacks may subside as the patient gets older.

Treatment.—Syphilis, malaria, lead and tobacco, as potential factors, furnish, when present, direct indications for treatment. Measures to improve the general health, to strengthen the nervous system, and to protect the patient from worry and over-fatigue should be used. Attention to clothing and the choice of a suitable climate are matters for consideration. In case alimentary toxæmia is a factor every effort should be made to restore bowel function to normal. Care should be taken to avoid slight injuries, such as might result from tight boots and the cutting of corns or nails. Gentle massage and dry warmth to the extremities may be of benefit. Thyroid extract is worth a trial. Other drugs are of little value, though calcium lactate in 15-grain doses, given three or four times daily, has proved useful in some cases. The drug sometimes relieves chilblains. Protein shock produced by the intravenous injection of T.A.B. vaccine is sometimes of value. Subcutaneous or intramuscular injections of acetyl choline have been recommended. During an attack, physical and mental rest and warmth are required. The affected limb should be elevated and wrapped in cotton wool. Chloral, pyramidon or morphine may be required for the relief of pain. Electrical treatment is of value in many cases. According to Cumberbatch, the galvanic current is the most effective method. He employs diathermy as a preliminary measure when there is gangrene. This is followed by the use of the galvanic current after the necrosed portions have separated and the parts are completely healed. Treatment by the galvanic current lessens the frequency and severity of the attacks. He applies the kathode to the spine over the cervical (or lumbar) enlargement of the cord. The hands (or feet) are immersed in warm water and connected to the anode. A current of 20 to 25 milliamperes is passed for twenty minutes. Treatment is given three times a week. Sympathectomy, as for instance, excision of the stellate ganglion or the less drastic method of dividing the peri-arterial sympathetic fibres, is still on trial. The operation is beneficial, especially in young subjects before secondary changes in the structure of the vessels have taken place. The amount of cooling of the hands required to produce cyanosis is much greater after sympathectomy (Paterson Ross).

ACROPARÆSTHESIA

Definition.—A vasomotor neurosis, characterised by paræsthesiæ of the hands, especially affecting the finger-tips.

Ætiology.—The condition is usually observed in women, especially at the climacteric. It rarely occurs before the age of 30. It is frequently associated with a neuropathic diathesis and a lowered vitality due to any cause. General causes include inanition, anæmia and pregnancy. Local causes are exposure to cold, particularly cold water, or to alternate hot and cold water as experienced by washerwomen.

Symptoms.—The onset is insidious and the symptoms are almost entirely subjective. The affection is often limited to one hand or certain fingers, the toes rarely being affected. The patient complains of numbness, tingling, formication of the fingers or tenderness of the finger-tips. There may be slight loss of sensibility in the finger-tips and occasionally evident pallor.

Diagnosis.—The condition is readily distinguished from Raynaud's disease by the absence of local asphyxia. It is important to exclude any affections of the spinal cord, such as tabes dorsalis.

Prognosis.—The complaint tends to be continuous and persistent. The outlook regarding recovery is not good, unless the condition is due to a recognisable and removable cause. There are, however, no complications.

Treatment.—This is directed to the removal of the cause, and improvement of the general health and of the local circulation. Salicylate of soda and bromides are often helpful, and radiant heat and massage are of value.

ANGIO-NEUROTIC ŒDEMA

Synonym.—Quincke's Disease.

Definition.—A paroxysmal affection, characterised by the appearance of circumscribed œdematous swellings of the skin and subcutaneous tissues of transient duration. The mucous membranes are often affected.

Ætiology.—Heredity is an important factor. Osler reported the case of a family in which five generations had been affected, involving 22 members. The condition is more common in men than in women, and generally affects the young. Those attacked are usually of a nervous disposition. Neurasthenia, hysteria, asthma, and rarely exophthalmic goitre are associated conditions. Garrod has reported a case in which each recurrence of periodic hydrarthrosis was attended by circumscribed œdema, either of the lips or eyelids. The attacks may coincide with menstruation. The exciting cause is generally difficult to determine. It may be emotional strain, exposure to cold, or trauma. Local trauma sometimes determines not only the onset but the site of an attack, as in a case recently reported in which riding provoked an attack on the inner aspect of the thighs and knees.

Pathology.—In the absence of a known pathology various theories have been advanced to explain the condition. Local venous spasm, a direct nervous influence on capillary walls, as a result of which the permeability of the vessels is increased, and, more recently, the local action of a circulating

toxin on the capillary walls, are theories which have obtained support. With regard to the last named, Garrod has drawn attention to the joint swellings that frequently accompany erythematous and urticarial rashes resulting from known toxic causes. Such conditions form a part of the clinical picture of serum sickness, or may occur after taking certain articles of diet, or as the result of stings of insects or nettles. Lewis has shown that a modification of the same toxin may produce a dermolysin or a hæmolysin. In the former instance œdema, in the latter purpura results. Thus, *B. welchii* may produce either condition, depending on the intensity of the infection. This thesis illustrates the present view of angio-neurotic œdema as being a local expression of the presence of a circulating toxin, prone to occur in persons of nervous temperament, rather than a disease *sui generis*. The patients often show other signs of allergy, especially in their sensitiveness to foreign proteins.

Symptoms.—The complaint takes the form of acute circumscribed swellings of the skin and subcutaneous tissues, 1 to 4 inches in diameter. The swellings are rounded, painless, rarely itch, and are generally pale or sometimes redder than the surrounding skin, from which they stand out prominently. They may develop simultaneously in different parts of the body, and disappear in a short time. They may recur repeatedly, or only after a period of years; the recurrence is occasionally periodic. They occur most commonly in the eyelids, lips, cheeks and backs of the hands, and are asymmetrical. The whole side of the face, one side of the scrotum, the penis, a whole limb, or in fact any part of the skin, may be involved. The pharynx, tongue and conjunctivæ may be implicated. Œdema of the glottis is rare, and has proved fatal. Swelling of mucous membranes may lead to symptoms of gastro-intestinal disturbance, such as nausea, vomiting and abdominal pain (colic). Cases in which hæmorrhage from mucous membranes, stomach, bronchi, bladder, etc., occurred have been reported. Hæmoglobinuria has been observed; in such a case a Wassermann test is indicated. The attacks are generally afebrile, and there is no constitutional disturbance, unless the stomach or intestine is involved.

Course.—This is variable. Recurrence is frequent, often at intervals of 3 to 4 weeks, but sometimes after long intervals. It is rarely periodic.

Diagnosis.—The complaint is so characteristic, in the sudden onset and rapid subsidence of asymmetrical rounded swellings, that it is hardly likely to be confused with other affections. The condition is nearly allied to urticaria, from which it is distinguished by the circumscribed and deep-seated nature of the swellings and the absence of itching. No distinction is made between angio-neurotic œdema and giant urticaria.

Treatment.—The general health must receive first attention, and a saline purge is indicated. Both arsenic and quinine have been advocated. It is advisable to avoid any particular protein in the food which is found to excite attacks. When the attacks occur after a particular meal of the day, a capsule containing 1 to 2 grains of peptone half an hour before that meal appears to have an effect in temporarily desensitising the body against foreign protein. This, combined with 5 to 7½ minims of the tincture of belladonna and 10 to 15 grains of calcium lactate after meals, has prevented recurrences in several cases. The former drug diminishes the vagal hypersensitiveness, and the latter increases the viscosity of the blood. One of the

most useful forms of treatment for the relief of the paroxysm is a subcutaneous injection of 3 to 7 minims of liquor adrenalini hydrochloridi. This excites the antagonistic action of the sympathetic. For the same reason half a grain of ephedrin orally administered may be tried. When the tongue is involved the patient should be given one or two of Armour's suprarenal tablets to suck. Pituitrin injections have also been recommended. Bromide is often helpful as an additional measure when the symptoms are marked. In severe cases the intravenous injection of small doses of peptone might be considered. Autohæmotherapy has proved useful in some cases.

Intermittent Hydrarthrosis, which is described fully under "Diseases of the Joints" (p. 1341), presents some interesting affinities with the vasomotor neuroses, particularly in its association with angio-neurotic œdema.

ERYTHROMELALGIA .

Definition.—A rare condition characterised by pain, redness and swelling of the toes and feet, and less often of the hands.

Ætiology.—Little is known of the ætiology of the disease. Men are more often affected than women. The condition may occur in the course of a disease of the central nervous system, such as hemiplegia, disease of the cauda equina, and disseminate sclerosis. The swelling and pain are aggravated by standing and by warmth.

Pathology.—Disease of the peripheral arteries—a chronic endarteritis—has been described in three cases by Batty Shaw. Changes in the peripheral nerves have been held responsible, and Weir Mitchell found marked degeneration of the fine nerve branches in one case. Others regard the malady as an angio-neurosis, allied to acroparæsthesia and Raynaud's disease, and possibly due to a primary disturbance of the vaso-dilator nerves. The suggestion has also been put forward that it is due to a spinal disease involving the lateral grey matter of the cord.

Symptoms.—The first case was described by Weir Mitchell, and was that of a sailor, aged 40, whose first complaint, following an African fever, was of "dull, heavy pains at first in the left, and soon after in the right foot. There was no swelling at first. When at rest he was comfortable, and the feet were not painful; after walking the feet were swollen. They scarcely pitted on pressure, but were purple with congestion; the veins were everywhere singularly enlarged, and the arteries were throbbing visibly. The whole foot was said to be aching and burning, but above the ankle there was neither swelling, pain . . . nor flushing."

Pain is generally the first symptom, soon followed by redness and swelling, most marked in the terminal phalanges of the toes or fingers. The pain is generally severe; at first it occurs only in the evening, but later it becomes chronic or remittent and may be agonising. The redness may increase to cyanosis. The swelling is more marked in the latter part of the day, and is aggravated by standing, walking, dependence of the limb and by heat. These symptoms are relieved by cold and recumbency. Hyperidrosis of the affected part is not uncommon. The condition may be complicated by general weakness, vertigo, headache, palpitations and tachycardia. Its complication with erythræmia has been described.

Prognosis.—The complaint is intractable, and tends to persist, with exacerbations and remissions, for many years.

Treatment.—The affected part should be elevated and immobilised. Faradism and cold have been recommended. Analgesics are required for the relief of pain, which may even necessitate amputation (Shaw). Sympathectomy is contra-indicated and should never be performed for this condition.

MILROY'S DISEASE

Synonym.—Hereditary Oedema.

Definition.—In 1892 Milroy described a persistent oedema of the legs, occurring in the absence of any of the known causes of oedema, affecting members of the same family in successive generations.

Ætiology.—The disease has occurred in six generations of the same family, but the percentage of incidence in the families has varied greatly. It is apt to appear in neurotic families. Both sexes are affected about equally, and the oedema may either appear soon after birth, or its onset may be delayed till puberty or even till adult life. Thirty-five years after his original description, Milroy found that the disease was tending to die out in the family in which he first observed it.

Pathology.—Nothing is known of the pathology of the condition. There is no evidence of venous or lymphatic obstruction.

Symptoms.—Only the legs are affected, and these to a variable extent. Thus the swelling may be limited to the ankles; it usually does not extend beyond the knees, but may reach the thighs in long-standing cases. It never extends above Poupart's ligament. Gradually the affected part becomes hard and brawny. The swelling increases in the standing posture, and, once established, it is permanent. There is no pain or redness, the veins are not enlarged, and the general health is not affected.

In some cases there are acute attacks accompanied by fever and pain. During this phase the condition resembles erythromelalgia.

Diagnosis.—This is made on the familial incidence, and the absence of all other recognised causes of oedema. A group of cases in which there is swelling of the feet, ankles and legs without albuminuria or discoverable organic disease to account for the swelling, has recently been recognised by Osman. The patients we have seen have been women in the third decade. The swelling is pale, brawny and does not pit on pressure. It may respond to rest in bed and intensive alkali therapy.

Prognosis.—The affection does not tend to shorten life.

Treatment.—The affected parts should always be kept bandaged with crêpe, as by this means the swelling can be kept under control, and the patient remains able to lead an active life; but if such measures be not employed the oedema gradually extends. Acute attacks may require opium internally, and evaporating lotions locally.

W. LANGDON BROWN.
GEOFFREY EVANS.

SECTION XV

DISEASES OF THE RESPIRATORY SYSTEM

THE PHYSICAL SIGNS IN THE CHEST IN HEALTH AND DISEASE

ACCURATE diagnosis in diseases of the air-passages and lungs depends very largely upon careful observation and record of physical signs, especially in their relation to subjective symptoms. Unfortunately, there is no strict uniformity in regard to the nomenclature of physical signs. It is, therefore, desirable to define explicitly the sense in which the various technical terms used in this section are employed. At the outset, it is well to emphasise the importance of a careful and methodical examination in every case. The magistral sequence of inspection, palpation, percussion, auscultation and mensuration has more than the sanction of tradition to commend it. Unless confined to bed, the patient should be examined both in the erect and recumbent positions in all cases of difficulty.

Inspection.—The patient being placed in a good light, the configuration of the chest, the range and character of the respiratory movements, and the position of the cardiac pulsations should be carefully noted. Most of the terms used in this connection, such as flattening, retraction, recession of intercostal spaces and diminished movement are self-explanatory.

The respiration may be unduly slow or rapid. Quickening of the rate is referred to as hyperpnœa, and if associated with distress—as dyspnœa.

Dyspnœa may be inspiratory, expiratory, or spasmodic. A peculiar periodic disturbance of the respiratory rhythm is that referred to as Cheyne-Stokes breathing. In this condition, the respiratory movements wax and wane in short periods of dyspnœa, each followed by an interval of apnœa or cessation of respiration lasting up to 30 or 40 seconds. It is due to deficient aeration of the blood and is met with in respiratory, cardiac and renal disease, and also in cerebral lesions and after some poisons.

A variety of grouped breathing is Biot's breathing, sometimes seen in tuberculous meningitis. The hyperpnœic period consists of a few breaths, deep or of increasing depth, followed by apnœa without the waning.

Certain abnormal forms of chest configuration are described: The *alar*, *phthinoid* or *ptyergoid* type of chest is long, narrow and flat, with winging of the scapulæ; the subcostal angle is narrow and the upper interspaces are wide. The *emphysematous* or barrel-shaped chest is broad and rounded, the angle of Ludovici is prominent, the subcostal angle is wide, and the movements are restricted. The *pigeon breast* is characterised by prominence of the sternum, with sloping anterior thoracic walls. The *funnel breast* is

the converse of this, with depression of the lower end of the sternum and of the cartilages attached to it.

Palpation.—Vocal fremitus or tactile fremitus is the vibration felt over the lung when the hand is placed flat upon the chest-wall without pressure and the patient says "ninety-nine" or some other resonant syllables. Vocal fremitus may be increased, decreased or absent in disease.

Tussive fremitus.—The similar vibration felt during cough.

Rhonchal fremitus.—The vibrations communicated to the chest-wall by sonorous rhonchi and felt by the hand in bronchitis.

Friction fremitus or pleural fremitus.—A rubbing sensation communicated to the palpating hand in certain cases of dry pleurisy. A similar fremitus is occasionally felt in pericarditis.

Percussion.—This consists in tapping the chest-wall over the lung and observing the note produced and the sense of resistance felt. Percussion may be *direct* on to the chest-wall or *mediate*, when the tap is made on to a finger or an instrument placed on the chest. The applied finger or instrument is called the pleximeter, the tapping finger or instrument, the plessor. Percussion should always be light, except over very muscular parts of the chest.

Normal resonance is the note obtained over healthy lung tissue.

Hyper-resonance is an increased resonance, with diminished sense of resistance obtained over emphysematous lung tissue.

Dullness is diminution or loss of resonance, with increase in the sense of resistance. Various degrees of dullness are described, such as impaired percussion, slight dullness, flat, wooden or stony note.

Tympanitic resonance—a hollow drum-like note.

Skodaic resonance—a clear, high-pitched note intermediate in character between the hyper-resonant and tympanitic notes.

Cracked-pot sound—or *bruit de pot fêlé*—a hollow note with a slight jingle added to it, obtained by smart percussion over a fair-sized cavity. It is also heard on percussion of a crying baby.

Auscultation.—The breath sounds should be listened to first, then the adventitious or added sounds, and lastly the vocal resonance.

BREATH SOUNDS.—The following varieties of breath sounds may be differentiated :

Vesicular breathing.—The normal respiratory murmur or faint rustling sound audible during inspiration and expiration, the former phase being two or three times as long as the latter. The pause between inspiration and expiration is short.

Cog-wheel, jerky or interrupted breathing is a form of vesicular breathing in which inspiration waxes and wanes, or is divided into two or more parts.

Harsh, exaggerated or puerile breathing.—An intense form of vesicular breathing heard in children and in some forms of emphysema.

Vesicular breathing with prolonged expiration.—There is no alteration in the intensity or pitch of inspiration, but expiration is more prolonged and often harsher.

Absent, diminished, weak and suppressed breathing are self-explanatory.

Bronchial breathing.—The pitch of both inspiration and expiration is raised. Expiration is as long as inspiration and is separated from it by a distinct pause.

Broncho-vesicular and vesiculo-bronchial breathing are incomplete forms of bronchial breathing in which inspiration or expiration respectively assume the bronchial type.

Tubular breathing is a peculiar form of high-pitched bronchial breathing of whiffing character, sounding as if produced close under the stethoscope. This term is often used as if synonymous with bronchial breathing, but should be restricted to breathing of the type just described, which is only heard in consolidation from lobar pneumonia and broncho-pneumonia and in collapse of the lung, including that form associated with pleural effusion.

Cavernous breathing is bronchial in type, but both inspiration and expiration have a peculiar hollow character. Expiration is hollower and more prolonged than inspiration.

Broncho-cavernous breathing is incomplete cavernous breathing, inspiration being bronchial, while expiration is cavernous.

Amphoric breathing.—An intense form of cavernous breathing, often having a very hollow metallic sound.

ADVENTITIOUS SOUNDS.—These were formerly divided into dry and moist. The former are now called rhonchi, the latter râles.

Rhonchi are musical sounds produced by the passage of air over mucus or muco-pus in the bronchi. Those arising in the larger tubes are called sonorous rhonchi, those in the smaller tubes sibilant or whistling rhonchi.

Râles are bubbling or crackling sounds produced in the bronchi or alveoli by the passage of air through fluid exudate or secretion. They are usually divided into bubbling and crackling râles. Bubbling râles are heard when the lung tissue is still spongy. Crackling or crepitant râles are produced in consolidated or softening areas of lung. Both varieties are arbitrarily subdivided into fine, medium and coarse râles. Crepitant râles are sometimes referred to as "creps"; this practice may lead to confusion with crepitation and is better avoided. Crepitant râles were formerly called consonating, bubbling râles non-consonating. Gurgling râles are coarse, low-pitched râles, usually heard over a cavity, especially after a cough.

Crepitations are fine "hair-like" crackling sounds. They may be produced either in the pleura or in the lung. In the latter they occur only in pneumonia, broncho-pneumonia, collapse and œdema. They are heard chiefly with inspiration and may be increased in number and intensity by coughing. A coarse variety heard in resolving pneumonic lung is called *redux crepitation*.

Pleural crepitations are fine sounds of similar character occurring in the early or dry stage of pleurisy. They are heard rather towards the end of inspiration and are usually unaffected by cough.

Friction is a coarse rubbing, creaking or grating sound heard in pleurisy when there is rough exudate on the pleural surfaces. It may occur with either inspiration or expiration or with both.

Stridor is a loud, coarse sound, heard chiefly during inspiration in cases of obstruction of the larynx, trachea or main bronchi. It is louder and lower pitched than a rhonchus.

Post-tussive suction is a hissing sound, audible directly after cough. It is heard only over a cavity, and is caused by the influx of air to replace that expelled by cough.

Veiled puff of Skoda or Laennec is a puffing sound heard towards the end of inspiration. It is said to indicate small and sacculated bronchiectatic dilatations.

Metallic tinkling and amphoric echo are terms used to describe the quality of certain sounds produced near a very large cavity or a pneumothorax, in breathing or coughing, or by the heart's action. The latter is practically a low-pitched variety of the former.

Succession splash is a splashing sound produced in a hydro- or pyopneumothorax by shaking the patient, or getting him to shake his thorax. If a gastric splash can be excluded, it is pathognomonic of a pleural or subphrenic hydro- or pyopneumo-thorax.

Bell sound or *bruit d'airain*.—A ringing sound heard on auscultation over a pneumothorax or any large cavity when a coin placed flat on the chest-wall over the air-containing space is tapped by a second coin. A similar sound is often audible on flicking with the finger and thumb over the chest-wall under similar conditions.

VOICE SOUNDS or Voice Conduction.

Vocal resonance is the muffled sound on listening over normal lung when the patient articulates "ninety-nine" or some other resonant syllables.

Bronchophony is an increase in the intensity of the normal vocal resonance.

Pectoriloquy is conduction of the articulate voice sounds which are clearly heard as if spoken into the stethoscope. It is best appreciated by auscultating the whispered voice, and is then called whispering pectoriloquy.

Ægophony denotes a peculiar bleating or nasal modification of the voice sounds, sometimes present on listening to them through fluid in the pleural cavity.

Physical examination of the chest includes mensuration, estimation of vital capacity and examination by the X-Rays when these are necessary.

Vital capacity is determined by a spirometer, which measures the amount of air which can be expired by a full expiration after the deepest possible inspiration. The average for an adult man is about 3600 c.c. The vital capacity is diminished in many diseases of the respiratory system, notably in acute pneumonia, pulmonary tuberculosis and in attacks of asthma.

R. A. YOUNG.

G. E. BEAUMONT.

DISEASES OF THE NOSE

ACUTE CATARRHAL RHINITIS

Ætiology.—This affection is part of a coryza or "cold," which is, in all probability, an infectious disease. One or more of the types of organism ordinarily present in the throat are found to be greatly increased in numbers; such organisms are the streptococcus, pneumococcus, micrococcus catarrhalis, Pfeiffer's and Friedländer's bacilli, the diphtheroids, and staphylococci. The clear watery discharge found at the onset of a cold may be almost germ-free, and the true cause of coryza may be a filter-passing ultra-microscopic virus, as seems now to be proved by Dochez' work in New York. Its ætiology

is largely a matter of the relative susceptibility of the subject and virulence of the invading organism; this virulence is increased by passage through a susceptible person who often imports colds into a household, and then infects the less susceptible members. The incidence is greatest in childhood, with the exception of infancy, and diminishes with advancing years. Chilling of the body lowers the resistance, and, of all things, a draught in a hot ill-ventilated room most predisposes to infection; but an open-air life is the best safeguard against catching cold. Acute rhinitis is also a symptom of the infectious fevers, especially of measles and influenza.

Symptoms.—At first there is a feeling of dryness and discomfort in the nose or naso-pharynx, with malaise and with or without fever, followed by nasal obstruction, watery discharge and often lachrymation and sneezing. Later, the discharge becomes muco-purulent. The entire attack usually extends over a period of 2 weeks, but a chronic rhinitis may be set up and persist indefinitely. Vasomotor rhinorrhœa closely resembles the acute stage of a coryza, but is much more variable and transient.

Complications.—In simple cases, and more often in those due to the infectious fevers, acute inflammation of the accessory nasal sinuses, or of the ears, may occur. In some patients the inflammation regularly extends down the throat and causes laryngitis, tracheitis or bronchitis.

Treatment.—This is often disappointing, and few persons will take the trouble to treat a cold efficiently, but singers and other professional voice-users, as well as patients subject to bronchitis, should submit to treatment. In the earliest stage, it is possible to abort a cold by obtaining free diaphoresis; the patient should be warmly wrapped up in bed and take hot drinks, with or without alcohol; quinine, 5 grains every 2 hours for 3 or 4 doses, or 10 grains of Dover's powder; the essential oils of the odoriferous plants are excreted by the respiratory tract, and are much used in this connection; onions are a household remedy, cinnamon is efficacious in large doses, 1 drachm of the essence in hot milk several times a day, and menthol and eucalyptol may be used in an atomiser. Especially after the early stage is passed, spraying or syringing the nares with warm normal saline, or with Dobell's solution, relieves discomfort and tends to prevent the discharge from becoming purulent.

The frequency and severity of attacks may often be diminished in highly susceptible persons by inoculations with an autogenous vaccine prepared from organisms derived from the patient's nasal secretion or by a "stock" vaccine containing the usual causative germs. A course of three or four increasing doses should be given before the end of September, to avoid the danger of the negative phase during an epidemic, and a further maintaining dose should be given once a month through the winter and spring, as the immunity is short-lived.

CHRONIC CATARRHAL RHINITIS

Ætiology.—Simple chronic rhinitis appears to result from frequently occurring attacks of coryza, or even from the persistence of a single acute attack. Predisposing causes of this persistence are deficient resistance, local irritation, auto-intoxication from the gastro-intestinal tract, and reflex vasomotor disturbance. Thus we find chronic catarrh associated with

anæmia, stuffy and over-heated rooms, occupations involving inhalation of irritating dust or vapour, excessive smoking, snuff-taking (a commoner habit than is generally realised among shop-assistants and clerks who are prevented from smoking during working hours), dyspepsia and constipation, alcoholism, sexual excess and masturbation. Nasal obstruction is an important factor in keeping up chronic catarrh by preventing ventilation of the passages, allowing mucus to collect and encouraging the growth of micro-organisms. In children the presence of adenoids is the commonest cause of catarrh.

Symptoms.—The symptoms are nasal obstruction and excessive secretion, which may be watery or muco-purulent, and may come forwards to the nostrils or pass backwards into the throat ("post-nasal catarrh"). Secondary results, from the extension of the inflammation, include catarrhal and suppurative otitis media, pharyngitis, laryngitis and bronchitis.

The nasal mucosa may be reddened, but often has a pale, sodden appearance. The turbinals are swollen and are at first quite soft, but later, when definite thickening has occurred, they feel firmer, and no longer shrink after the application of cocaine or adrenaline. At this stage the condition may be called "hypertrophic rhinitis," and the mucosal thickening, most marked over the two ends of the inferior turbinals and over the lower margin of the middle turbinal, may form large lobulated masses.

Diagnosis.—The diagnosis, in cases of hypersecretion, can only be made after excluding by rhinoscopic examination all other causes, such as a foreign body, mucous polypus, syphilitic, tuberculous and lupoid ulceration, and, more especially, suppuration in any of the accessory sinuses; in the latter, the discharge is not scattered over the nasal passages, but emerges in a localised stream from one or other of the ostia and reappears in the same situation after being removed. The discharge of chronic rhinitis is bilateral, and, though often muco-purulent, is never true pus. The diagnosis from vasomotor rhinorrhœa is often difficult; the symptoms of the latter come and go with great suddenness, often as a result of definite causes such as going into a hot room, and there is complete absence of symptoms between the attacks. A bacteriological examination is often helpful.

Treatment.—General treatment, directed to the predisposing causes mentioned above, is necessary if a good result is to be obtained. Next, nasal obstruction must be removed, and operative treatment is called for if the cause be adenoids, deviation of the septum, or great hypertrophy of the extremities of the inferior turbinal bodies. For details, the reader is referred to surgical works; but it must be emphasised that the valuable secreting surface of the nasal mucosa must not be recklessly sacrificed, and that large portions of inferior turbinal must on no account be removed, nor should every slight deviation of the septum be submitted to operation, for it is rarely quite straight. When the turbinal enlargement is soft and shrinks after the applications of cocaine, the galvano-cautery should be used under local anæsthesia to draw one or two lines along the length of the inferior turbinal, the result of which is to produce a scar binding the mucosa to the bone. When the case has not gone on to definite hypertrophy, the most valuable form of local treatment is cleansing of the nasal passages. The lotion must be warm, about 90° F., and quite unirritating; for this reason it should have approximately the same specific gravity as serum, and normal

saline solution does very well. A mildly antiseptic and alkaline lotion is usually to be preferred, of which Dobell's solution is the type, such as sodium bicarbonate, grs. iij; sodium chloride, grs. iij; carbolic acid, gr. i; glycerine, ℥ xlv; water, ℥ i. A convenient instrument for the purpose is a small rubber ball of a capacity of 2 oz. with a blunt nozzle moulded in one piece, which is slowly emptied into the nostril, while the patient breathes deeply through the mouth and inclines the head forward over a basin; in this way the palate is raised and the lotion passes through the naso-pharynx and out by the other nostril. The nose must not be violently blown afterwards, nor must any force be used during syringing, or fluid may be injected into the Eustachian tubes. Occasionally syringing causes headache, in which case the lotion may be used in a coarse spray-producer. Chronic nasal catarrh is, however, in certain cases notoriously resistant to treatment, especially under the conditions of civilised town life; indeed, many sufferers found themselves better in the wet and exposed conditions of life in the trenches during the Great War. Vaccine therapy is uncertain in its effect, but gives good results in a proportion of cases; an autogenous vaccine should be prepared from the patient's nasal secretion.

RHINITIS SICCA

This is a condition which results from failure of the nasal mucosa to secrete enough fluid to saturate the inspired air without itself becoming dry, and is frequently accompanied by dryness of the pharynx and larynx.

Ætiology.—The cause is found in any constitutional disturbance which interferes with free nasal circulation and secretion, such as anæmia, dyspepsia or alcoholism, and in breathing unusually hot dry air, as by cooks or stokers. As a temporary disturbance it is a usual accompaniment of any febrile condition.

Symptoms.—Small dark scabs of dry mucus are found especially where the current of air most impinges, on the front end of the middle turbinal and more particularly on the anterior inferior portion of the septum. In the latter situation the scabs are removed by blowing or picking and leave a small erosion, which is the commonest source of epistaxis. Sometimes the septal cartilage is completely perforated; this, the so-called "idiopathic perforation," is smooth and round and always limited to the cartilage, which serves to distinguish it from syphilitic perforation which usually involves the bony septum; the perforation due to lupus is, like the idiopathic variety, limited to the cartilage, but can be distinguished, in the active stage, by the characteristic nodules and by coexisting lesions elsewhere.

Treatment.—This consists in dealing with the anæmia, constipation, etc., avoidance of dust and excessive alcohol or tobacco, and the use of an emollient spray, such as menthol, grs. x, paraffinum liquidum, ℥ i; or, for erosions on the front of the septum, an ointment, *e.g.* ung. hydrarg. nitrat., ℥ i, vaseline, ad ℥ i.

ATROPHIC RHINITIS

Ætiology.—Cases usually first come under treatment between the ages of 15 and 18, but its insidious beginnings date from an earlier age, and a history

of nasal discharge through childhood is often obtainable. It affects females at least three times as often as males. A peculiar physiognomy is to be noticed in nearly half the cases; the skull is brachycephalic, the nose wide and flat, and the nostrils broad, and so directed forwards as to be more than usually conspicuous. The affection is sometimes unilateral, in which case the septum is deflected, and the disease occurs on the wider side. Occasionally it is found among several members of a family, which might be the result of contagion, but it is also inherited in circumstances where contagion cannot apply, and this may be due to inheritance of the disease or merely of the predisposing physiognomy. Of the many bacteria found in association with the affection, the most important are the Klebs-Loeffler bacillus, the *Cocco-bacillus fetidus* of Perez, and the *Cocco-bacillus mucosus* of Beeritz, but the consensus of opinion is that they are secondary and, though helping to produce the fœtor, are not the primary cause of the disease. The condition occurs at too early an age to be the final stage of hypertrophic rhinitis, nor is it usually due to accessory-sinus disease, which can be excluded in the majority of cases. It is probably the sequel of prolonged purulent rhinitis in childhood, which results in the replacement of the ciliated by squamous epithelium, and thus destroys the principal agent for the removal of secretion; the undue width of the nasal passages promotes this retention by diminishing the force of the expulsive current of air, by drying the secretions and by unduly admitting dust and micro-organisms. In this way crusts of dried mucus are formed and decompose, and the resulting inflammation prevents the development of the turbinates and further increases the width of the nasal fossæ.

Pathology.—There is a chronic inflammation resulting in sclerosis and atrophy of the mucosa; the ciliated epithelium is replaced by squamous, the mucous glands are degenerated and the venous sinuses have disappeared. These changes are most marked over the inferior turbinates, and the middle turbinates are frequently large and oedematous. The discharge is not pus, but mucus precipitated by evaporation, mixed with shed epithelial cells and teeming with micro-organisms. This collects and dries into large greenish-black crusts which give rise to the peculiar sweetish and horribly offensive odour. There is never true ulceration nor necrosis of bone.

Symptoms.—The symptoms are chiefly those of the nasal discharge and the offensive stench; the latter is rarely perceptible to the patient, who usually, in established cases, has complete anosmia. There are also obstruction from the crusts, dryness of the throat and cough, and often some degree of ill-health from toxic absorption.

The inside of the nose is full of crusts; the inferior turbinates are reduced to mere ridges, the mucosa is pale and thin, and through the widened nasal passages the body of the sphenoid and the wall of the pharynx are plainly visible.

Complications.—Infection of an accessory sinus may result by extension from the septic nasal cavities, but is not very common; conversely suppuration of the sphenoidal or a posterior ethmoidal cell is a possible, and has been considered by some authorities as the usual, cause of the affection. The lymphoid tissue of the throat is conspicuously absent; there is often a dry pharyngitis and laryngitis, and sometimes the crusting extends to these parts, or even down the trachea. Catarrhal and suppurative otitis are

common, and the disease is thought by many to predispose to pulmonary phthisis.

Prognosis.—As the ciliated epithelium can never be replaced, the affection is not truly curable, though regular treatment can keep it in an inoffensive condition, and it is common to see a suggestive degree of atrophy of the turbinals in young people with rhinitis completely disappear under treatment. Also, the crusting tends to become less troublesome as time goes on and ultimately to cease, a state of things which is difficult of explanation.

Treatment.—The nose must be kept clean by regular syringing with a mild alkaline antiseptic lotion, of which a large quantity should be used with a Higginson syringe provided with a fine nozzle which cannot block the nares. An oily, stimulating or emollient application, such as oleum eucalypti 15 minims to 1 ounce of paraffinum liquidum, or a 25 per cent. solution of glucose in glycerine, may be painted or sprayed into the nose. The crusting can be prevented by excluding the air, and when syringing is insufficient, this should be done by introducing a plug of gauze or cotton wool loosely into the anterior nares, which should be changed twice a day by the patient. After some weeks of treatment the packing may be omitted, but resumed in the event of a relapse. When the surgeon removes the plug the discharge is seen to be a clear mucus; if pus be found, it must be traced to its source in an accessory sinus. Paraffin wax may be injected under the mucosa, to narrow the nasal passages, but it is liable to slough out, and a piece of costal cartilage has been implanted with the same object. A plastic operation has been devised to shift the antro-nasal wall inwards and has given encouraging results. The treatment of anæmia is important; good food and an open-air life, especially at the seaside, are beneficial.

MEMBRANOUS OR FIBRINOUS RHINITIS

The Klebs-Loeffler bacillus produces in the nares two very different clinical conditions: a true nasal diphtheria which is then usually of a severe type, and a purely local affection known as fibrinous rhinitis. This latter occurs in children and is not associated with any marked constitutional disturbance nor followed by paralysis; it appears to be slightly infectious, as such, but not to give rise to true diphtheria, and therefore does not require notification.

Treatment.—The treatment consists in cleansing the nares with the usual mild alkaline lotion, and a spray of liquid paraffin; strong antiseptics and forcible removal of the membrane only do harm, and antitoxin is useless.

EPISTAXIS

Ætiology.—The causes of epistaxis may be classified as follows:

Local causes.—Traumatism, including blows on the nose, fracture of the base of the skull, surgical operations, foreign bodies; the small septal erosion of rhinitis sicca, which is the commonest of all causes; malignant disease; angio-fibroma, or "bleeding polypus," of the septum; multiple telangiectasis, a curious hereditary affection characterised by numerous minute dilations of the capillaries on the face and mucous membranes of the nose, mouth

and throat; the general congestion caused by adenoids; and syphilis, lupus and the rarer granulomata, though in these the bleeding is usually an insignificant symptom.

General causes.—High blood-pressure, as in arterial disease, chronic nephritis, cirrhosis of the liver, violent exertion, extremes of heat and cold, congestion at the menstrual period, or “vicarious menstruation”; venous congestion, as in mitral stenosis, tumours in the thorax or root of the neck, emphysema, bronchitis and whooping-cough; toxic blood conditions, as pernicious anæmia, leukæmia, purpura, scurvy, and all the acute infectious fevers, especially in the prodromal stage. To these may be added rarefaction of the air, as in acroplane ascents and mountaineering, and poisoning by some drugs, especially salicylates and quinine.

The *source of the bleeding* is, in the large majority of cases, a small spot, called Little’s or Kisselbach’s area, situated on the front and lower part of the septum just beyond the vestibule.

Treatment. Epistaxis, of sufficient severity to call for the attention of the doctor, should always be treated, though it is of course of comparatively little importance in healthy young people; in older patients with high blood-pressure the loss of blood may be beneficial, but the occurrence is so distressing and alarming to the patient that other means to lower the pressure should be adopted.

The source of the bleeding is usually so far forward that a pledget of wool introduced for less than an inch into the naris, and held by compressing the nostrils, will generally control it temporarily. To arrest it and prevent recurrence the bleeding spot must be found, started if necessary with a probe, controlled by application of cocaine and adrenaline on a plug of wool, and sealed by the galvano-cautery at dull-red heat. The use of an emollient ointment during the separation of the scab is advisable. In obstinate cases the bleeding may recur from another spot or from the opposite naris, when the treatment must be repeated. As in other forms of hæmorrhage, a rapid excited heart’s action, associated with restlessness and fright, is often present, and an injection of morphine is of great value. Calcium lactate is often recommended and may be given in 20-grain doses three times a day for 2 or 3 days; or colloidal calcium may be injected subcutaneously. If the bleeding is from the usual situation, formal plugging of the nose is seldom called for; but sometimes the bleeding proceeds from farther back in the nose, or is so profuse that its situation cannot at first be determined. In such cases the naris should be evenly packed with ribbon-gauze introduced on forceps under inspection. The older method of plugging the posterior nares is seldom required. Nasal plugs quickly become septic, and should ordinarily be removed in 24 hours; but they may be kept sweet for several days, should it be necessary to retain them, by moistening them frequently with peroxide of hydrogen.

MUCOUS POLYPUS

Ætiology and Pathology.—Nasal polypi are rare before puberty and are somewhat commoner in men than in women. They never grow from the septum, inferior meatus or inferior turbinal, but only from the ethmoidal region and interior of the accessory sinuses. They are not neoplasms, but

are essentially due to a local œdema of the mucous membrane ; the swelling thus produced is acted upon by the expulsive forces of the nose, and, being so pulled down and elongated, the return flow of its blood vessels and lymphatics is further impeded and a greater degree of œdema results. All stages of polypus formation may be found, ranging from an œdematous fringe along the border of the middle turbinal to enormous pedunculated masses which block the nose and expand its bony walls. In the great majority of cases the œdema is due to inflammatory infiltration of the muco-periosteum of the ethmoidal labyrinth and is often associated with inflammation in the ethmoidal cells ; sometimes, however, the cause is vasomotor disturbance, for polypi are found in cases of hay fever and paroxysmal rhinorrhœa in the absence of true inflammation. There is also another form, the so-called "choanal polypus," in which a large single polypus hangs into the nasopharynx from a long pedicle attached within the antrum and passing through the ostium into the nose.

Symptoms.—The cardinal symptoms are nasal obstruction and discharge, which is profuse and watery. The symptoms are worse in damp weather. Cough, headache and asthma are not infrequent, and a loss of the power of mental concentration often occurs.

Polypi are smooth, shiny, white, translucent bodies, pedunculated and extremely soft and movable to the probe ; their appearance is so characteristic that they cannot properly be mistaken for anything else. If they project into the nostril they become pinker and more opaque.

Treatment.—The best method of removal is in most cases with a wire snare, a process which can be rendered quite painless with skilful manipulation and the application of cocaine. Any polypoid mucosa in the neighbourhood should be removed with punch-forceps, but the application of caustics or the cautery only does harm. Recurrence is common, but becomes less rapid if the new polypi are removed at regular intervals before they have grown large. Inflammatory disease in the ethmoidal cells and other sinuses must, of course, receive treatment. In the worst cases, the polypi are so numerous and return so rapidly that the snare cannot deal with them adequately ; in such they should be removed with a ring-knife or suitable forceps under general anæsthesia, together with the softened ethmoidal tissue, and any suppurating sinuses be opened at the same time.

PAROXYSMAL OR VASOMOTOR RHINORRHOËA

In this condition fits of sneezing are associated with a profuse watery nasal discharge, irritation of the nasal and conjunctival mucosa, nasal obstruction, and often marked depression and prostration. The discomfort is usually worse in the morning, in overheated rooms, or on going out into the cold. The rapidity with which the attacks come and go is sufficient to distinguish them from an ordinary coryza. The affection usually shows itself in early adolescence and tends to improve with advancing age ; it is distinctly hereditary and may be associated, either in the patient or in his relations, with asthma, urticaria or chilblains. Males and females are equally affected, and it is most frequent among the cultivated classes ; a mental shock is sometimes the starting-point of the attacks.

Of these cases, *hay fever* is the best known and most marked variety, and is due to specific susceptibility to a proteid substance contained in the pollen of certain grasses; in this country, attacks begin about the end of May and terminate in August. Hay-fever subjects are affected by very minute quantities of this toxin, whereas ordinary people are completely immune. Other individuals are susceptible to the pollen, seedlets or scent of other plants and flowers, and others again to the emanations from horses, cats, dogs and other animals; and researches show that asthma, urticaria, eczema or rhinorrhœa may be variously produced by many kinds of proteid substances, including common and uncommon articles of diet, such as eggs or lobsters, in certain people who are specifically susceptible to these substances.

Treatment.—The determining factors, which should receive attention, are heightened irritability of the nervous system, occasionally some intranasal abnormality which increases the sensitiveness, and the specific irritant. Nerve tonics, strychnine, arsenic and valerian, are indicated, and attention to the general health. Hay-fever patients are better in a locality as free as possible from pollen; some remain comparatively well at the seaside, others only on board ship, while some have to spend the best days of the year in a darkened room. Occasionally great benefit results from the removal of some nasal abnormality, a polypus or a sharp spur impinging on the turbinal, but the result of operative treatment is uncertain. In most cases the nares are normal, and in many of these a light cauterisation of the most sensitive areas is very helpful; the sites usually chosen are on the upper anterior part of the septum, and on the anterior part of the inferior turbinal. True hay-fever patients may have their susceptibility to pollen lessened by inoculation with diluted extract of pollen; the use of these extracts, standardised under the name of *pollaccin*, gives excellent results in a proportion of cases, and, more recently, the attempt has been made to test susceptibility to, and to immunise against, other proteid poisons.

ACCESSORY-SINUS SUPPURATION

Ætiology.—In the large majority of cases infection reaches the accessory sinuses from the nasal cavity, and may result from a simple coryza or from one of the acute infectious fevers. Influenza is especially liable to produce disease of the sinuses, which may also be caused by measles, scarlet fever, erysipelas, enteric, pneumonia or small-pox. In addition, antral suppuration is caused by infection from the teeth, particularly the second bicuspid and first two molars, whose sockets are in closest proximity to the antral floor. The discharge from one sinus readily enters and infects another, so that disease of several cavities often coexists.

Symptoms and Diagnosis.—If the ostium of a suppurating sinus be occluded the pus is secreted under pressure, and the local symptoms are severe, whereas if the secretion can escape freely there may be no symptoms except discharge. The former class of case has been called "closed" and the latter "open" empyema. The difference between the two is, however, only relative, and many cases are alternating, the severe symptoms being relieved by periodical discharge. As the pressure of the pus in the cavity depends on

the rapidity of its secretion, and the degree of occlusion of the ostium by inflammatory swelling, it follows that the closed and open cases correspond generally to acute and chronic suppuration; acute suppuration is usually fairly obvious, but some chronic cases with scanty secretion are only to be detected after very careful examination and may be for long the undiscovered cause of post-nasal catarrh, pharyngitis or chronic toxæmia.

The symptoms, then, are swelling, pain, tenderness and discharge, together with the secondary effects of the suppuration. Swelling is rare; the bony walls are not bulged by an empyema, and this is a point of distinction between it and a tumour or cyst, but occasionally spread of the inflammation causes periostitis, or a fistula in the bone is formed leading to an abscess outside the sinus. Thus, in frontal sinusitis a swelling may appear at the junction of the inner and upper walls of the orbit, displacing the eye downwards and outwards, or an abscess may form here and, after opening, leave a fistula. Similarly, ethmoidal disease may produce a swelling farther back on the inner wall of the orbit, displacing the eyeball outwards. In antral empyema, a little œdema of the cheek, or slight swelling in the canine fossa, may be found, but a swollen cheek is more likely to be due to dental periostitis, while any definite bulging of its bony walls is an indication of a tumour. Pain is often severe in acute cases, and in chronic suppuration there may be considerable neuralgic pain. Pain of an intermittent character, relieved by a sudden gush of discharge from the nose, is highly characteristic of sinus disease, as also is a peculiar periodicity, for it tends to begin regularly at the same time every morning and to get better during the afternoon. The pain may be of a local inflammatory character, or may be referred to various parts, and of a neuralgic type. In antral suppuration it is over the cheek, or may be referred to the teeth or frequently to the supra-orbital region. The pain of frontal sinusitis is over the cavity or along the supra-orbital nerve; that of ethmoidal disease is over the nasal bridge, behind the eye or in the temple, and in sphenoidal suppuration, in the middle of the head, behind the eye, on the vertex or in the occipital region. Tenderness can usually be elicited in frontal empyema by percussion over the anterior wall, and especially by pressing upwards against the floor of the cavity; it is less marked in antral disease, in the canine fossa. Discharge into the nose is the most important, and often the only, symptom. A localised stream of pus in the nose, which reappears after removal, is, in the absence of a foreign body, conclusive evidence of suppuration in an accessory sinus. The differentiation of the affected sinus is made by following the pus to its source with a probe and, in the case of the antrum, by tapping with a trocar and cannula. The antrum, frontal and anterior ethmoidal cells open into the middle meatus, and the posterior ethmoidal and sphenoidal into the superior meatus. Further assistance is afforded by transillumination and skiagraphy. Fœtor, both subjective and objective, is often present, and a serious degree of anæmia and ill-health frequently result.

Complications.—These include pharyngitis, laryngitis, bronchitis, and otitis media; the swallowed pus causes various forms of gastric and intestinal disorders, including appendicitis. Acute septicæmia and pyæmia are rare, but symptoms of chronic poisoning, such as arthritis and fibrositis, are common. A very important series of complications results from extension of the inflammation to surrounding parts: orbital abscess or cellulitis, osteo-

myelitis of the frontal bone, cerebral abscess, thrombosis of the cavernous sinus, paralysis of the oculo-motor nerves and, from the sphenoidal sinus, papilloedema and optic atrophy.

Treatment.—This, in acute cases, consists in rest in bed, hot fomentations to the affected part, aperients, a light diet, and a few doses of aspirin. Inhalations of mentholised steam at frequent intervals are of value, and may be prepared by adding 10 drops of 25 per cent. solution of menthol in spirit to a pint of steaming water in an inhaler. In recent cases of antral suppuration, the cavity should be tapped with trocar and cannula and washed out with a warm saline lotion; this should be repeated daily or every two or three days, according to the severity of the disease, and will effect a cure in a large proportion of cases in an early stage. Frontal sinusitis has a greater tendency to spontaneous cure; the anterior end of the middle turbinal should be amputated and occasionally a cannula can be passed and the cavity washed out. Cases which fail to recover under such treatment, and those of chronic suppuration, must be submitted to operation.

SYPHILIS

CONGENITAL SYPHILIS

The *early form* appears at any time within 3 months after birth, usually within the first few weeks. The symptoms, frequently called "the snuffles," are those of nasal discharge and obstruction; the former may be thin and ichorous, or purulent and bloodstained, and is often associated with cracks and excoriations about the nostrils, upper lip and angles of the mouth; the obstruction may cause attacks of choking and frequently prevents the baby from taking the breast, and so produces wasting and malnutrition. These symptoms are not pathognomonic of syphilis, but may also be caused by catarrhal and purulent rhinitis, therefore the diagnosis must be established by the concomitant lesions.

The *late form* appears usually about the period of puberty, but may occur at any time after the age of about 5 years. It is characterised by a slow destructive gummatous infiltration and ulceration, and the symptoms are those of nasal catarrh and obstruction, frequently with fœtor and crusting; this chronic rhinitis destroys the ciliated epithelium, and may thus cause a true atrophic rhinitis which persists after the syphilis has become quiescent or cured. Congenital syphilis is apt to produce a very characteristic "saddle-back" flattening of the bridge of the nose.

ACQUIRED SYPHILIS

Primary chancre is sometimes seen on the ala of the nose, and is accompanied by bubo of the submaxillary and pre-auricular glands, and by much induration and swelling.

Secondary syphilis does not produce noticeable symptoms in the nose; there may be rhinorrhœa and obstruction associated with hyperæmia of the mucosa.

Tertiary syphilis occurs usually in the form of a diffuse gummatous

infiltration and ulceration, which may proceed to necrosis of any of the bony or cartilaginous walls of the nose; there is profuse purulent discharge, often bloodstained, which tends to dry into greenish-black crusts, the odour of which is extremely offensive. A localised gumma may occur on the septum, where it forms a smooth round swelling projecting into both nostrils which, by its contraction after healing, produces a steep depression of the bridge just below the nasal bones. Syphilitic ulceration sometimes attacks the external parts of the nose, causing perforation of the ala or destruction of the columella, with a characteristic depression of the nasal tip.

Diagnosis.—This seldom presents much difficulty; the form with crusting and ozæna imitates atrophic rhinitis, but in the latter there is never necrosis or decided ulceration—indeed intranasal necrosis may be considered pathognomonic of syphilis. A septal gumma has an appearance identical with that of a hæmatoma, but without the sudden onset and history of traumatism. Syphilitic perforations nearly always involve the bone, whereas those due to rhinitis sicca or lupus never do. Some cases of diffuse infiltration resemble lupus; but in the latter there is no necrosis or offensive odour, the characteristic nodules are usually to be seen at the edges of the lesion, and other patches of lupus may be found on the skin or in the fauces. The chief difficulty of diagnosis lies between severe syphilitic infiltration and malignant disease, but it can usually be determined by the clinical appearance, especially by the characteristic edge of the syphilitic ulcer, by the examination of an excised portion, by the Wassermann reaction, and by the results of anti-syphilitic treatment.

Treatment.—General treatment must be very prompt and energetic to prevent irremediable deformity, and should ordinarily be begun with the injection of salvarsan or of one of its congeners. Of local treatment, the lesions should be kept clean by frequent syringing with a saline lotion, to which sanitas, lysol or listerine may be added when the odour is offensive, and any necrosed bone must be removed as soon as it is loose.

LUPUS AND TUBERCULOSIS

Ætiology.—With the exception of the rare occurrence of tuberculous ulceration as a terminal infection in advanced phthisis, the lesions produced in the nose by lupus and by tuberculosis are indistinguishable; it appears that the tubercle bacillus finds in the nasal mucosa a medium unsuitable for its development, its virulence is diminished, and it can only produce the modified lesions known as lupus. It is possible, also, that this modification of the bacillus by its sojourn in the nose is the ordinary cause of lupus; at any rate it is frequently primary in the nares, whence it spreads to the fauces and larynx and on to the face and hands. The disease begins most frequently between the ages of 15 and 30, is twice as common in females as in males, and is usually seen in badly nourished people of the poorer classes.

Symptoms.—The early lesions are found on the antero-inferior part of the septum, the nasal floor and the front end of the inferior turbinal, within reach of the finger-nail, which probably conveys the infection. The characteristic "apple-jelly" nodules are seen, with or without ulceration, the

latter with rounded slightly raised margins, and tending to spread in some directions and cicatrise in others. The lesions are covered by small adherent scabs, and perforation of the septal cartilage is common. The alæ often become involved with destruction of the margin or with perforation, and the nostrils may be much narrowed and deformed by scarring, while the lachrymal duct is frequently involved. The progress of the disease is extremely slow and may continue over many years. The subjective symptoms are nasal obstruction with a slight sticky discharge.

Diagnosis.—The nares should be examined in all cases of cutaneous lupus, for, if the disease remain unhealed in the nose, relapses will continually occur. In the majority of cases of nasal lupus the diagnosis is cleared up by the presence of lesions or scars on the face, fauces or larynx. The difficulties of diagnosis are from rhinitis sicca with perforation, and from syphilis. The typical brownish nodules are pathognomonic and can always be found by careful examination when the lesions are progressing; they can be made more conspicuous by blanching the mucosa with adrenaline. The scabbing of rhinitis sicca quickly clears up under simple emollient treatment, while the lesions of syphilis are more rapidly progressive and tend to involve bone.

Treatment.—The affected areas are defined by the application of adrenaline and thoroughly and carefully scraped away with a sharp spoon, a general anæsthetic being employed if the lesions are extensive; small lesions and recurrences are destroyed with the galvano-cautery. Nascent iodine by Pfannenstiel's method may be employed; sodium iodide is given in 7-grain doses six times a day, while the nose is packed with gauze kept moist with peroxide of hydrogen, 10 volume strength, with 5 per cent. of acetic acid added; when a marked reaction has been obtained this solution should be diluted to half its strength, the iodide being continued as before; the treatment may have to be persisted in for several months. Radium is still under trial, and tuberculin has not established its value in this affection.

Of general treatment, arsenic in full doses, fresh air, cod-liver oil and fattening foods are of value. Lupus does not show the same tendency to spontaneous cure in the nose as in the larynx; it is easy to obtain improvement, but complete cure is very difficult.

TUMOURS

Papilloma occurs on the skin lining the vestibule and differs in no respect from cutaneous warts elsewhere. On the nasal mucosa it is excessively rare, occurs usually on the septum, has a narrow pedicle, a rough red or greyish surface, and bleeds readily when touched; occasionally the growths are multiple, and, when large, are difficult to diagnose from a malignant growth. but they do not erode the bones; they tend to recur locally after removal.

Fibroma, similar to the naso-pharyngeal fibromata, occurs, though rarely, as a smooth pink growth attached to the posterior region of the nares. It bleeds readily and spontaneously and demands great caution in removal.

Angio-fibroma, or "bleeding polypus of the septum," is less uncommon. It varies from the size of a pin's head to that of a filbert, is red or purple, smooth or finely lobulated, sessile or pedunculated, and grows from the

1072 DISEASES OF THE RESPIRATORY SYSTEM

anterior part of the septum. The prominent symptom is epistaxis, for the tumour bleeds freely and spontaneously. When pedunculated, it may be removed with the snare and the base cauterised; when sessile, it should be stripped off the underlying cartilage with an elevator. Recurrence is common.

Osteoma and *enchondroma* are extremely rare, and usually grow from the ethmoid region and produce obstruction and deformity.

Cysts.—Mucous polypi are occasionally cystic; the so-called "ethmoidal cyst" is an enlarged cell in the anterior part of the middle turbinal pressing on the septum and causing obstruction and headache. True cysts are sometimes seen on the anterior part of the nasal floor, and arise from the roots of incisor teeth. When small, they may be treated by intranasal removal of part of the wall; when large, they should be dissected out from the gingival fold.

Malignant tumours occur in all varieties: carcinoma, sarcoma, and endothelioma. Though they sometimes appear on the septum or nasal floor, the usual site of origin is the ethmoidal region. They tend to expand the bones of the face, producing a characteristic frog-like deformity, and they frequently invade the antrum and expand its walls, constituting a common variety of tumour of the upper jaw. The facial, palatine and orbital walls of the antrum may each be bulged outwards, the latter with displacement of the eyeball, and egg-shell crackling can sometimes be elicited. Sanious discharge and free spontaneous hæmorrhage are prominent symptoms and important for diagnosis. Access to the deep parts of the nose for the removal of these tumours is obtained by lateral rhinotomy, or Moure's operation, by which an incision is made in the line of junction between the nose and face and the nasal process of the superior maxilla removed. Good access to the lower part of the nose without scarring is attained by Rouge's operation, in which an incision is made in the gingivo-labial fold from the molar teeth of one side to the other and the soft parts raised. A formal excision of the upper jaw rarely fits the case. A small proportion of cases have remained free from recurrence over long periods; in a much larger number the relief of nasal obstruction and pain has made the operation well worth while, and the whole area being thrown into one large cavity by removal of bony partitions enables it to be kept clean and diminishes pressure-pain. The implantation of radium needles has given encouraging results, access being obtained by lateral rhinotomy or by opening the antrum through the canine fossa.

HAROLD S. BARWELL.

DISEASES OF THE NASO-PHARYNX

ADENOIDS

Ætiology.—By this term is implied a chronic enlargement of the lymphoid tissue of the naso-pharynx, the "pharyngeal tonsil." This normally is present in childhood and disappears by the age of 20 or thereabouts, but if chronically enlarged may remain up to any age. The precise stage at which

the enlargement becomes pathological can only be determined by the symptoms which it produces ; these usually become manifest between the ages of 3 and 8, but occasionally show themselves at or soon after birth. The incidence of adenoids is universal, but they are most common in damp temperate climates, and there is no doubt that chronic or repeated attacks of nasal catarrh are the principal factor in the causation ; the infectious fevers, particularly measles, scarlet fever, and diphtheria, are also a frequent cause of the hypertrophy.

Pathology.—The adenoid, as it should really be called, or enlarged pharyngeal tonsil, is a mass of lymphoid tissue of definite anatomical shape ; it is thickest above and tapers away below, and presents a series of ridges which radiate from below upwards and slightly outwards. In older patients the mass is firmer and more fibrous, and the ridges are often adherent in places, leaving deep clefts and furrows in which secretion can collect and decompose.

Symptoms.—The symptoms of adenoids are many and various, and include those due to nasal obstruction, those caused by infection and by the extension of inflammation, and reflex processes attributable to irritation and lowered vitality. In infants the nasal obstruction interferes with sucking and a serious degree of malnutrition will result unless the baby be carefully spoon-fed. Older children snore at night, breathe heavily in the day, and either bolt their food or eat very slowly owing to the necessity of breathing through the mouth. Owing to lack of oxygen the patients sleep restlessly, wake unrefreshed and often suffer from a peculiar inability to concentrate the attention sometimes called "aproxexia." Persistent nasal obstruction during the period of growth mechanically produces permanent deformities of the jaws and face which narrow the nasal passages, prevent the mouth from closing naturally and thus perpetuate mouth-breathing. When the mouth is habitually held open, the *alæ nasi* are pulled downwards with the cheeks, and become narrow and slit-like and fall in like valves with each inspiration ; this "alar collapse" is an important cause of obstruction in neglected cases of adenoids. The palate is narrow and highly arched ; the dental arch is narrow and V-shaped, so that the upper incisors, crowded and prominent, look outwards rather than forwards, and are not covered by the short upper lip ; the lower jaw retains its infantile obtuse angle, and the lower incisors lie behind the upper ; the chin is receding and, in the worst cases, when the molar teeth come into contact on biting, the incisors cannot meet. Only a proportion of cases of adenoids show these deformities, and there is, indeed, considerable uncertainty as to the importance of adenoids in their *ætiology* ; undue softness of the bones, such as occurs in rickets, is doubtless an additional factor, and also in the causation of the malformations of the chest which result from the obstruction to the entry of air. The long narrow unexpanded chest with acute costal angle and prominent scapulæ is the commonest deformity. Harrison's sulcus, a transverse depression corresponding to the attachment of the diaphragm ; pigeon-breast, a prominent sternum with depressed costal cartilages ; and funnel-breast, a sharp depression at the lower end of the sternum, are also encountered.

Various infective processes result from the spread of inflammation and, if the naso-pharynx be large, are not necessarily associated with nasal obstruction. The terribly common catarrhal and suppurative affections of the ear in children are, in an overwhelming majority of cases, the result of

adenoids. Blepharitis and phlyctenular conjunctivitis are also associated with adenoid vegetations. Feverish attacks, often with tender enlargement of the cervical glands, are caused by infection of the pharyngeal and faucial tonsils, and tuberculous disease of the glands is usually due to passage of the bacilli through these portals; in such cases the tonsils and adenoids may remain unaffected or may themselves show tubercles under the microscope. Chronic or recurrent bronchitis frequently results from the infection spreading to the lower air-passages. The mucus secreted by the adenoids is swallowed in large quantities, and produces derangements of stomach and intestines with failure of growth and general health. Finally, mouth-breathing undoubtedly predisposes to dental caries. The irritation of these vegetations, and their effect on respiration and the general health, account for numerous reflex and nervous disturbances. Among them may be enumerated laryngitis with spasm called "laryngitis stridula," spasm of the glottis without laryngitis or "laryngismus stridulus," stammering, reflex cough, asthma, night terrors and nocturnal enuresis; it should be stated that the latter disorder is by no means always to be cured by removal of the concomitant adenoids, and that in general too much stress must not be laid upon the presence of adenoids as the causative factor in all these reflex disturbances.

Diagnosis.—In the majority of tractable children a view of the naso-pharynx can with patience be obtained with a good light and a very small rhinoscopic mirror, when the upper part of the septum and the concavity above it are seen to be occupied by an irregular convex mass. Where this is impossible a rapid digital examination may be required; this is extremely unpleasant to the little patient, and may be postponed, in those cases where the tonsils are sufficiently large to call for removal, until the child is anæsthetised. Similarly, in very frightened, intractable children, if the symptoms point strongly to adenoids it is wiser to give an anæsthetic for examination, being prepared to remove the vegetations if present. In the mongolian type of idiocy the tongue is large and the mouth persistently open, and in microcephaly the extremely undeveloped naso-pharynx causes nasal obstruction; cases of both these types of maldevelopment are often brought to the doctor in the hope that removal of their adenoids will cure their "backwardness," and care should be taken not to fall into the error of performing a useless operation, though if a well-marked adenoid be present it should be removed under a guarded prognosis. On the other hand, adenoids can be present and produce serious secondary effects without causing nasal obstruction or any appearance of the typical "adenoid facies."

Treatment.—The normal naso-pharyngeal tonsil becomes swollen during a coryza, and such temporary swelling should not be diagnosed as "adenoids," by which term chronic hypertrophy is understood, and does not call for removal provided that it subsides promptly, does not frequently recur, and is not associated with otitis media or other important complications. In such cases, and when the only symptom is a mild catarrh, the regular use of a simple warm saline lotion with a rubber ball-syringe (see p. 1057) will often effect a cure; in children below the age of 5 or 6 syringing is apt to be difficult and the lotion may be used in a spray, while in infants it is best to drop it into the nostrils from a small pipette like the filler of a fountain-pen. This treatment should be combined with open air—if possible a change to the seaside or a bracing country district—cod-liver oil, iodide of iron, or arsenic. Breath-

ing exercises are of great value in these slight catarrhal cases, but only do harm where there is marked obstruction.

When the enlargement frequently recurs or has gone on to chronic hypertrophy, operative removal is the only treatment, and this is especially called for when any aural symptoms supervene, or when cervical adenitis is present. After operation the general treatment referred to above is valuable, but the nose should on no account be syringed until healing is complete, as this encourages aural complications. If the alæ nasi are collapsing, or the chest narrow, breathing exercises are of use, but healthy open-air occupations are more useful still. In patients in their teens, or upwards, turbinal hypertrophy has not infrequently resulted; the surgeon should be prepared to snare off enlarged posterior ends of the inferior turbinals at the time of the operation, and intranasal cauterisation may be required later.

TUMOURS

Innocent tumours in the naso-pharynx are exceedingly rare; the so-called "choanal polypus" is a variety of nasal mucous polypus which hangs into the naso-pharynx from a long pedicle attached within the nares.

Fibroma of the naso-pharynx, or naso-pharyngeal polypus, occurs usually in males between the ages of 10 and 25, grows by a broad pedicle from the periosteum of any part of the walls of the naso-pharynx, usually from the basi-sphenoid, and forms a smooth, rounded, pink mass which fills the naso-pharynx and sends prolongations into the nasal cavities. The palate is pushed downwards, the bones of the face expanded, and the eyeballs separated and displaced, producing the "frog-face" deformity. The cardinal symptoms are nasal obstruction and discharge, with headache and severe epistaxis; aural complications may follow, or the eyes may be involved with diplopia, exophthalmos and compression of the optic nerve; and, finally, death results from exhaustion, hæmorrhage, sepsis or cerebral invasion. Histologically the tumour is composed of fibrous tissue containing numerous thin-walled blood vessels and a variable admixture of round or fusiform cells, so that in some cases it might be described as a fibro-sarcoma; but it is not truly malignant, for it neither involves the glands nor becomes disseminated, though there is a tendency to local recurrence after removal.

During surgical removal the bleeding is terrific, but quickly ceases when once the pedicle has been detached; rapid operation is therefore important. The tumour must be removed by separating the pedicle from its attachment with special stout elevators, and may be reached through the mouth, or through the nose after lateral rhinotomy has been performed, according to its site of origin. It cannot be approached satisfactorily through the anterior nares and, on the other hand, division of the soft palate is unnecessary. A preliminary laryngotomy is advisable. Radium has proved of considerable value in reducing the size and vascularity of these growths, as a preliminary to operation.

Dermoid tumours occur as pathological curiosities in the naso-pharynx.

Malignant tumours are not common in the naso-pharynx, but epithelioma, sarcoma and endothelioma all occur. The early symptoms are chiefly pains of a neuralgic character and those produced by Eustachian obstruction;

later, epistaxis, nasal obstruction, secondary involvement of glands and affections of the eye and cranial cavity may appear. Removal by operation is rarely feasible, but occasionally a growth of limited size may be attacked through the lateral rhinotomy route. Sarcomata and endotheliomata in this region sometimes yield remarkably to treatment by radium.

HAROLD S. BARWELL.

DISEASES OF THE LARYNX

ACUTE CATARRHAL LARYNGITIS

Ætiology.—The affection ordinarily occurs as part of a coryza, or cold, the inflammation spreading downwards from the nose or naso-pharynx. It is also caused by over-use of the voice, especially with faulty voice-production, and frequently a slight catarrh is made worse by using the voice during a cold. It occurs in many infectious fevers, *e.g.* influenza, measles, scarlet fever, typhoid and small-pox, and it is occasionally a result of traumatism, instrumentation, or the inhalation of irritating fumes in chemical works or of the gases used in warfare. Predisposing causes are chiefly those factors which favour attacks of coryza, such as nasal obstruction or discharge, sedentary occupations and overheated rooms; apart from local tuberculous lesions, consumptives are very subject to laryngeal catarrh.

Symptoms.—The symptoms consist of hoarseness or aphonia, local discomfort varying from dryness or tickling to a burning sensation or actual pain, and sometimes an irritable cough. There is little expectoration, unless the trachea is involved. At the onset there may be slight feverishness and malaise. The degree of hoarseness is by no means proportionate to the objective appearances; the voice may be quite good in cases of decided hyperæmia, and may be completely lost when little abnormal is to be seen. This depends largely on the neuro-muscular tone; a muscular man will retain a strong voice with a degree of inflammation which would render a weakly woman completely aphonic—indeed some women lose the voice with every slight cold, so that it becomes difficult to differentiate between laryngeal catarrh and “functional aphonia.” On the other hand, in some voice-users redness of the cords appears to be the normal condition and causes no interference with function. This variable effect on the voice is to be observed in all forms of laryngeal disease. In children, acute laryngitis is a serious affection. They show a far greater tendency to oedema and to spasm, and as the glottis is not only absolutely but relatively smaller than in adults, a dangerous dyspnoea may ensue with great rapidity. The larynx is reddened, and this is most obvious on the parts usually pale—the epiglottis and vocal cords, the vessels on the former being unduly prominent. The cords may be red, pink, yellowish, or merely have lost their bright pearly lustre. A small amount of mucous secretion is generally present, but no large accumulations or strings of mucus, such as are seen in chronic laryngitis; a minute globule of mucus may sometimes be seen standing on the centre of the cord during phonation, and resembles a little nodule. There is often a little swelling of the

cords so that, on phonation, their edges come into contact at the centre ; this explains how singers' nodules are caused by use of the voice during a laryngitis.

Treatment.—People suffering from the slighter degrees of laryngitis rarely apply for treatment, unless they are professional voice-users. The patient should remain in a warm (65° F.), well-ventilated room, preferably in bed, and must not attempt to use the voice. The coryza, if present, should be treated at the same time. Steam inhalations are of value and may be used from an inhaler or from a jug round the mouth of which a towel has been wrapped in the shape of a cone. The water should be at a temperature of 130° to 140° F., and one of the following medicaments may be added in the proportion of one drachm to the pint : Compound tincture of benzoin (Friar's balsam) ℥i, with or without menthol, grs. x-xv ; or benzoic acid, grs. iij, kaolin, grs. xij, tincture of tolu, ℥ xviii, and water to ℥i, these being sedative, while oleum pini sylvestris, ℥ xl, magnesii carb. levis, grs. xx, water to ℥i is mildly stimulating. Steam inhalations should only be ordered when the patient can remain in a warm room ; when he is not confined to the house, or in a later stage, an oily solution from an atomiser is preferable, such as menthol, grs. vii, camphor, grs. iij, chloretone, grs. v, liquid paraffin, ℥i. Internally, expectorants are indicated ; vinum ipecacuanhæ, ℥x, or vinum antimoniale, ℥v, potassium iodide, grs. ij or iij—singly or in combination—or ammonium chloride, grs. v, or oil of cubebs, ℥ v in syrup, every 4 or 6 hours. If cough is severe it should be restrained ; a lozenge of morphine and ipecacuanha is useful, or a linctus containing heroin hydrochloride, gr. 1, or liquor morphinæ, ℥ ij to iv.

The acute laryngitis of children calls for prompt treatment. One or two grains of calomel may be given every 3 hours until the bowels have acted freely, after which it may be continued in $\frac{1}{2}$ gr. doses three times a day. Hot fomentations to the neck and a steam-kettle are advisable, and in acute febrile cases, 1 minim each of tincture of aconite and vinum antimoniale every 3 hours. If dyspnoea occurs, an emetic dose of ipecacuanha often gives prompt relief ; 1 drm. of the vinum followed by $\frac{1}{2}$ -drm. doses every half-hour until vomiting occurs : in very young or weakly children, 15 minims every quarter-hour may be preferred.

SPASMODIC LARYNGITIS (LARYNGITIS STRIDULA)

This is simply catarrhal laryngitis with spasm of the glottis as a marked feature. It is a disease of childhood and is predisposed to by general ill-health, rickets and adenoids. The onset is that of an ordinary cold, with slight feverishness, hoarseness and a frequent cough, and during the evening or night the respiration becomes embarrassed. There is inspiratory stridor, recession of the epigastrium and lower ribs and, in some cases, an alarming degree of asphyxia. The symptoms tend to subside towards morning and, though they may recur on the next few nights, it is usually with diminishing severity. The condition should be distinguished from laryngismus stridulus, in which there is no hoarseness or other symptoms between the attacks. The evanescence of the symptoms serves to distinguish it from cedematous laryngitis and from diphtheria, in which the attacks become increasingly severe. The general health requires attention, and adenoids, if present, must be removed after recovery takes place.

CEDEMATOUS LARYNGITIS

Ætiology.—Œdema of the larynx is not a disease but a pathological condition due to a variety of causes. Non-inflammatory œdema may be mentioned here for the sake of completeness; it occurs, though rarely, as part of the general anasarca of renal and cardiac disease. Angio-neurotic œdema sometimes occurs in the larynx, in which event it produces rapid and severe dyspnœa (see p. 1052). The swelling which occasionally results from administration of potassium iodide in susceptible subjects may be placed in the same category.

Inflammatory œdema seldom results in adults from a simple catarrh, but it may do so in children; it more often occurs as part of an acute septic pharyngitis, and is often associated with “angina Ludovici.” Œdema may follow various forms of traumatism, the drinking of corrosive poisons in attempted suicide, inhalation of irritating vapours, such as the poison gases of the Great War, the lodgment of foreign bodies, or rough or unduly prolonged bronchoscopy. Scalding, from attempts to drink from a kettle-spout, is a common cause among children. In other cases it is a sequela of typhoid fever, pneumonia, scarlet fever or small-pox, and is a local complication of syphilitic, tuberculous, cancerous or traumatic ulceration.

Symptoms.—If part of a septic pharyngo-laryngitis, the general symptoms are severe. The chief local symptom is dyspnœa with inspiratory stridor and the associated symptoms of asphyxiation; there is hoarseness or aphonia, local discomfort and tenderness, and sometimes dysphagia. The aryteno-epiglottidean folds are enormously swollen, appearing as pale or purple translucent flask-shaped masses; if the epiglottis be œdematous it forms a sausage-shaped swelling of the same appearance. The mucosa of the vocal cords is too adherent to permit much swelling, and “œdema of the glottis” is therefore a misnomer. The subglottic region is lax and may become swollen; indeed, the œdema may be confined to this region and then appears as a red swelling below each vocal cord. In children œdema may be inferred from the steadily increasing dyspnœa without the rapid increase and decrease typical of spasmodic laryngitis.

Angio-neurotic œdema is a very rapid condition and has proved fatal.

Treatment.—In slight cases, the swelling may be reduced by sucking ice and by the application of an ice-bag to the neck; the latter is inadmissible in young children. A spray of adrenaline, 1 in 1000, may be used. Hypodermic injections of pilocarpine, gr. $\frac{1}{8}$, are recommended and, for the œdema produced by iodides, large doses of bicarbonate of soda. Free scarification of the œdematous tissues at the upper aperture should be practised without undue delay; in adults this should be done with a laryngeal lancet under guidance of the mirror, but in children it is best performed with a curved bistoury guarded to near the point with strapping and passed down along the left forefinger as a guide. If this does not give quick relief, or if the dyspnœa be severe, tracheotomy should be performed without delay, in adults under local anæsthesia. Intubation is not suitable for cases of œdema of the upper aperture of the larynx, though it may be employed for subglottic cases, provided that skilled attention be immediately available should the tube be coughed out. Angio-neurotic œdema should

be treated by a spray of adrenaline, and the same drug, or a colloidal preparation of calcium, may be injected hypodermically; tracheotomy may here also be required.

MEMBRANOUS LARYNGITIS

The formation of false membrane in the larynx is nearly always part of an attack of diphtheria, which is discussed elsewhere, but by the term "membranous laryngitis" is implied a formation of membrane of non-diphtheritic origin. Apart from traumatic cases, in which the membrane is due to irritating chemicals and scalds, inflammation of the larynx accompanied by membrane may be caused by streptococcal infection. The affection occurs especially in children between the ages of 2 and 8 years. The first symptom is hoarseness, soon followed by a brassy cough and the signs of dyspnoea; the patient is restless and the temperature rises rapidly to 103° or 104°. In some cases, however, the disease takes a subacute form, the attacks of dyspnoea being worse at night and abating towards morning. The diagnosis from diphtheria is only possible by bacteriological examination, and pending the report the case should be treated with antitoxin; but it may be noted that the pharynx is nearly always involved in diphtheria, whereas in membranous laryngitis the disease is often primary in the larynx. The prognosis is grave, worse than that of diphtheria since the introduction of antitoxin. An emetic dose of ipecacuanha should be given, and a steam-bath and hot fomentations to the neck are advisable. Calomel treatment is recommended; 1 or 2 grains every 3 hours until the bowels have acted freely, and subsequently 1 grain three or four times a day. Tracheotomy or intubation must not be delayed when there is serious dyspnoea.

PERICHONDritis

Ætiology.—This, an inflammatory exudation beneath the perichondrium of one of the laryngeal cartilages, usually going on to suppuration, is most frequently the result of infection with pyogenic organisms in the course of tuberculous, syphilitic or malignant disease of the larynx. It is found as a complication of typhoid fever, small-pox, or other infectious fevers, or of septic laryngitis; and it is also caused by traumatism from without or by a foreign body within, by the rough passage of the stomach tube, or by the introduction of a tracheotomy tube through the larynx.

Symptoms.—In acute cases there are the usual general feverish symptoms. Locally, there is pain and tenderness, with a variable degree of hoarseness, dysphagia or dyspnoea, depending on the site and severity of the inflammation. External swelling and abscess formation occur when the thyroid or cricoid cartilages are attacked.

Arytenoid perichondritis appears as a unilateral rounded swelling of this region; the infection generally enters at the vocal process, where the mucosa is thin and adherent and, when pus forms, the abscess ruptures here. When necrosis occurs, the entire cartilage may be exposed in a deep triangular cavity, which opens on its inner aspect. This form is a common complication

of tuberculous laryngitis. Epiglottic perichondritis produces a rounded red swelling, accompanied by severe dysphagia. In thyroid perichondritis, there is diffused swelling of the lateral wall of the larynx and ventricular band of the affected side, with early fixation of the vocal cord and hoarseness. Externally there is a tender swelling over the ala. The abscess may rupture into the larynx or ramify widely in the neck. Cricoid perichondritis usually affects the posterior plate, causing a swelling of the posterior laryngeal wall, with subglottic oedema, dysphagia and severe dyspnoea.

Treatment.—This depends largely on the cause. Abscesses should be opened when they form, either internally or externally, and necrosed cartilage removed when possible. Dyspnoea may call for tracheotomy and, later, cicatricial stenosis may demand treatment. When pain is present, aspirin and small doses of opium are required; insufflations of orthoform, 3 grains, or of orthoform and anæsthesine in equal parts, 15 minutes before meals, are helpful in relieving the pain of swallowing.

CHRONIC LARYNGITIS

Ætiology.—The causation is similar to that of acute catarrhal laryngitis; indeed, chronic laryngitis is often the result of recurrent or persistent acute catarrh. The principal factors which predispose to chronicity are nasal obstructions and discharges, dusty occupations and lack of fresh air, over-use of the voice and faulty voice-production, and the abuse of alcohol or tobacco; consumptives are particularly liable to non-specific catarrhal laryngitis, and oral sepsis must not be omitted. Almost any cause of general ill-health may be included among the predisposing causes, such as gout, rheumatism, anæmia, and gastro-intestinal, cardiac and hepatic disorders.

Symptoms.—The only constant symptom is impairment of the voice, which is hoarse, easily tired or even, though rarely, completely aphonic; it is sometimes weakest when tired in the evening, but is often at its worst on rising in the morning or after a rest. There is frequently a sensation of aching, dryness, tickling or of a lump in the throat, and there is usually some cough, but little expectoration, unless the trachea and bronchi are involved.

The objective appearances vary with the severity of the affection. The larynx generally is of a deeper red than usual, and the vocal cords have lost their normal pearly lustre and are pink or grey; they are usually somewhat thickened at the edges, and enlarged vessels may be visible on their surface; the vocal processes are often prominent and may be reddened or show up white against the hyperæmic cord. Strings of sticky secretion may stretch between the cords, or a little globule of mucus may form on the centre of the cord during phonation; adduction is frequently imperfect. When the epiglottis is reddened, its yellow edge stands out clearly and enlarged vessels are seen on the surface; the ventricular bands are often swollen so as to hide the outer part of the cords. The mucous membrane in the interarytenoid space, thickened and relaxed, is seen to be thrown into folds on adduction of the cords, and may form a mass large enough to prevent their approximation.

Atrophic rhinitis usually produces a form of inflammation, *laryngitis*

sicca, in which small brown scabs adhere to the cords and posterior commissure, but occasionally the disease itself spreads to the larynx, which is covered by large greenish or brownish-black fœtid crusts; more rarely still the crusts extend into the trachea and cause severe dyspnoea, which may prove fatal.

Pachydermia laryngis is a somewhat rare variety of chronic laryngitis, occurring principally in middle-aged men. It is frequently ascribed to alcoholism, perhaps on insufficient grounds, to syphilis and to tubercle; the diagnosis between pachydermia and these two diseases is, however, often a matter of difficulty. The characteristic epithelial thickenings are probably of the nature of corns, resulting from frequent cough and continued irritation. There is hoarseness of a rough raucous character, but no particular discomfort. The epithelial thickening is pink or whitish and occupies the posterior or cartilaginous region of the glottis from the vocal processes backwards to the posterior commissure. A circumscribed swelling appears on each vocal process, with a small cup or depression at the apex; the approximation of the cords is better than would be expected, because the prominence on one vocal process fits into the depression at the other. The epithelium of the inter-arytenoid space is thrown into ridges, which fill up the angles between the arytenoid and the posterior commissure, but leave a depression in the middle line. These firm, opaque, symmetrical swellings, without ulceration, are distinguishable from the soft irregular granulations of a tuberculous lesion; and the even cup-shaped swelling on the vocal process, even when more marked on one side, should not be mistaken for an early epithelioma.

Treatment.—The detection and correction of the ætiological factors are the most important part of treatment. Any constitutional disturbance, such as anæmia, rheumatism, gout or dyspepsia, should receive attention. Over-indulgence in tobacco, or alcohol, lack of ventilation and exposure to dust must be considered, and with teachers the black-board chalk is a common source of irritation.

Incorrect voice-production is a factor of great importance especially, but by no means exclusively, among those who use the voice largely in their occupations; in such, a course of lessons in voice-production often works wonders. In a large proportion of cases the primary cause of the laryngitis is to be found in the nose, therefore any source of nasal obstruction, catarrh or suppuration must be carefully looked for and treated; any concomitant pharyngitis should also receive attention.

Locally, treatment must begin with rest of the voice, which should be absolute in the case of professional voice-users. Where there is much secretion a saline lotion may be used in a spray—sodium bicarbonate, sodium biborate, sodium chloride, 10 grains of each, thymol water, 2 drms., glycerine, 1 drm., water to 1 ounce. Oily solutions are usually preferred, such as menthol, 5 grains, camphor, 2 grains, chlorotone, 5 grains, or oil of eucalyptus, pine of gaultheria in similar proportions to an ounce of liquid paraffin. The direct application of pigments is not often called for, and is to be recommended only when pachydermatous changes are present; in such cases the cautious application of a solution of nitrate of silver on a cotton-wool mop once a week may be tried, beginning with 5 grains to the ounce and increasing the strength gradually to 50 or more grains. Dundas Grant advises an

1082 DISEASES OF THE RESPIRATORY SYSTEM

alcoholic solution of salicylic acid, beginning with 1 per cent. and increasing to 6 or 8 per cent.

Internally, small doses of potassium iodide, 2 or 3 grains, or the yellow proto-iodide of mercury, $\frac{1}{18}$ grain, three times a day over long periods, are of value.

CONGENITAL LARYNGEAL STRIDOR

In this condition there is an exaggeration of the infantile shape of the upper aperture of the larynx; the epiglottis is sharply folded laterally, the ary-epiglottic folds are almost in contact, and the opening is thus reduced to a narrow vertical slit. As these parts are very flaccid in infancy, they become sucked together during inspiration and, by their vibration, produce the characteristic stridor. This stridor is noticed very soon after birth, it is inspiratory, of a peculiar purring or even musical character, and is most marked during active breathing and crying. The voice is unaffected, and there is remarkably little sign of dyspnoea or distress. These characteristics distinguish the condition from other forms of obstruction found in infants, such as laryngeal webs or papillomata, or "thymic asthma." It tends to disappear during the second year of life, but the prognosis must be guarded in early infancy, for an attack of bronchitis is more than ordinarily dangerous and even kills a proportion of these patients.

SYPHILIS

CONGENITAL SYPHILIS

The early, or secondary, form appears in the first few months of life and is rarely recognised, but it may be suspected when the cry is hoarse in an infant with active syphilitic lesions.

Tertiary lesions are rare, and usually make their appearance about puberty, less often during the second dentition. The disease takes the form of diffuse infiltration with or without ulceration; the swelling may produce obstruction or, later, cicatricial stenosis may ensue. The symptoms are stridor with hoarseness, and tracheotomy may be required.

ACQUIRED SYPHILIS

Symptoms.—Secondary lesions are superficial, cause no symptoms but hoarseness, and seldom come under observation. The commonest manifestation is an erythema which differs from that of catarrhal laryngitis by being more uneven and patchy in its distribution, and may affect one cord, leaving the other normal. Mucous patches are occasionally found on the cords or on any part of the larynx, appearing as superficial erosions with a smooth greyish base and a sharply defined hyperæmic margin. The fauces are nearly always affected at the same time.

Of tertiary lesions, the superficial serpiginous ulcer is occasionally seen with the same characters with which it more commonly appears on the

fauces. Diffuse infiltration may attack any part of the larynx, but chiefly, in contra-distinction to tuberculosis, the anterior regions, such as the epiglottis and the front parts of the vocal cords. Subglottic infiltration is fairly frequent and abduction of the cords often limited, so that stenosis is much commoner than in tuberculous disease. The typical circumscribed gumma is distinctly rare; it is single, unilateral, and attacks especially the epiglottis and arytenoids, and usually breaks down rapidly to form a deep excavated ulcer, which may result in perichondritis, exfoliation of cartilage, and, ultimately, in severe cicatricial stenosis. The subjective symptoms are hoarseness, of a peculiar rough, "raucous" character, and sometimes dyspnoea with stridor; pain is in general not a prominent symptom, but a gumma on the upper aperture may cause severe dysphagia.

Diagnosis.—From tuberculous disease the diagnosis is discussed under that heading (see pp. 1084, 1085). From epithelioma a gumma is distinguished by its more rapid evolution; the edge of an epithelioma is thick and everted and its base nodular, whereas these characters are less marked in syphilitic ulceration, the margin of which is hyperæmic and frequently sharply cut; while other parts of the larynx or fauces often show syphilitic lesions. The hard infiltration of secondarily involved glands is characteristic of malignant disease.

Treatment.—General treatment is urgently called for to prevent perichondritis and stenosis. Local treatment is not often required. Tracheotomy should be performed when decided dyspnoea is present; it seems to aid the recovery of the larynx, and the tube can often be omitted in a short time, when anti-syphilitic medication has removed the obstructing lesion. Necrosed pieces of cartilage must be removed by internal or external operations, and insufflations of orthoform are indicated when dysphagia is present.

LUPUS

Lupus in the larynx is comparatively rare, and is probably always secondary to the disease in the nasal passages.

Symptoms.—The lesions begin on the epiglottis and slowly spread along the aryteno-epiglottic folds; the interior of the larynx is less often attacked and the cords usually escape. The infiltration is composed of tiny red nodules, which develop the typical "apple-jelly" centre and break down to form multiple coalescent shallow ulcers, the smooth base covered by a scanty secretion and with indefinite uninflamed margins. Cicatricial contraction goes on during the progress of the affection, and the epiglottis, if not destroyed, is usually much deformed; but the scars are less thick, and the contraction less severe than in syphilis, and marked stenosis is less common.

Treatment.—The disease shows a decided tendency to spontaneous cure, and in many cases of cutaneous lupus the scars of healed disease can be seen in the larynx. Open-air treatment, as carried out in a sanatorium, with good food, moderate exercise, and cod-liver oil suffice to cure most cases. Arsenic, in large doses, appears to have a specific effect, starting with 5 minims of liquor arsenicalis 3 times a day and increasing the dose gradually to 15 or more minims. Local treatment should be reserved for those cases which general measures fail to cure. If the lesions are confined to the epi-

glottis, this may be removed ; for more diffuse infiltration repeated galvanocautery puncture gives the best results, but over-zealous application will promote stenosis. Good results have recently been reported from the use of radium, applied externally to the neck in the form of plates.

TUBERCULOSIS

Ætiology.—Primary tuberculosis of the larynx is so rare as to be of no practical importance ; in the overwhelming majority of cases the disease is secondary to pulmonary tuberculosis, of which it is a common and important complication. It is probably caused by infection from the sputum, is two or three times commoner in men than in women, and is most frequent between the ages of 20 and 40. StClair Thomson finds that the difference in sex-incidence is occupational, and that women, working in office and factory are as susceptible as men.

Symptoms.—The disease attacks, in order of frequency, the vocal cords, arytenoid region, inter-arytenoid space, ventricular bands and epiglottis ; in general the lumen is invaded before the upper aperture, and the posterior rather than the anterior parts of the larynx. The typical infiltration is finely nodular, pallid and soft in appearance ; ulcers are shallow, with a smooth speckly base and pale ill-defined margin. On the vocal cord the disease chiefly attacks the posterior half and especially the vocal process, where ulceration readily reaches the underlying cartilage and may produce a deep triangular excavation. Thickening in the inter-arytenoid region is common ; infiltration of the arytenoids results in typical pale semi-translucent flask-shaped swellings, while the epiglottis appears as a firmer red sausage-shaped mass.

Of subjective symptoms, the hoarseness is very characteristic, the voice being weak and effortless and very different from the raucous voice of syphilis. Cough and expectoration are mostly due to the pulmonary disease and not in any considerable degree to the larynx. Pain on swallowing is common and often very intense ; there may also be actual obstruction to deglutition and, in a late stage, entry of food into the larynx. Dyspnoea is rare.

Diagnosis.—Although signs of pulmonary tuberculosis are helpful in diagnosis, it is obvious that any kind of laryngeal disease may occur in a consumptive patient.

From simple laryngitis.—In the earliest stage of invasion tuberculous laryngitis may exactly resemble catarrh, but redness of one cord only is certainly not due to catarrh, and the latter quickly improves under treatment. The swollen arytenoids of oedematous laryngitis are less pale and more transparent, while the affection is acute and the entire larynx inflamed. Inter-arytenoid infiltration resembles pachydermia, but the latter is opaquely white, firm and symmetrical.

From lupus, typical tuberculosis differs completely. The former is painless, affects first the epiglottis and upper aperture, is never accompanied by oedema, and tends to cicatrization. But there is a chronic "lupoid" form of tuberculous laryngitis which attacks the epiglottis and is very similar to lupus.

From syphilis.—The tuberculous ulcer has an ill-defined margin without

surrounding hyperæmia; the base has a yellow speckled appearance, and on healing there is little scarring or contraction. The superficial syphilitic ulcer has a well-defined hyperæmic margin, with a smooth, flat base; the deep ulcer is "crateriform," with thickened punched-out edge, and, on healing, leaves a dense scar and marked deformity. In general, syphilitic lesions attack the anterior half of the larynx, tuberculous the posterior; the former look firm and dense, the latter soft, translucent and ill-defined.

From neoplasms.—Only the rare tuberculomata resemble innocent tumours. Occasionally tuberculosis attacks one vocal cord in an elderly patient, and may then easily be mistaken for epithelioma (see p. 1088).

Prognosis.—Any tuberculous lesion of the larynx renders the prognosis of a case of pulmonary tuberculosis much more serious. A considerable number of the superficial lesions become healed; but it is doubtful if any cases of extensive infiltration recover, with the exception of a few rare instances where it is confined to the epiglottis and can be entirely removed.

Treatment.—Tuberculous laryngitis is but a complication of pulmonary tuberculosis, and by far the most important part of the treatment is that of the general infection. For the laryngeal lesions the most valuable remedy is complete silence, but it is a severe and depressing measure and should not be insisted on unless there is a prospect of cure; the pain and irritation in advanced cases are, however, often relieved by vocal rest. Any concomitant catarrh should receive attention; an oily spray containing menthol and chloretone (7 grains of each in an ounce of liquid paraffin) is valuable, and irritable cough should be relieved by a simple lozenge, or, if severe, by heroin, $\frac{1}{2}$ gr. or less in a lozenge or linctus. Attempts to cure by active local treatment must only be made when the pulmonary lesions are quiescent or progressing towards arrest, the general health good, and the local lesions not very extensive. Of these methods the galvano-cautery is the most generally useful, and may be employed to the surface of superficial ulcers, or as multiple puncture of infiltrated areas. Chemical caustics may be applied to ulcerated surfaces, especially on the cords and posterior commissure; lactic acid, 50 to 80 per cent., may be used, or Lake's mixture of lactic acid 50 per cent., formalin 7 per cent., and phenol 10 per cent. Ulcers covered with sprouting granulations may be curetted, and occasionally infiltration of the epiglottis or arytenoid may be removed with punch-forceps.

In advanced cases the dysphagia is so distressing that its relief is of great importance. For this purpose the most valuable drug is orthoform, which may be combined in equal proportions with anæsthesine; it is an insoluble non-toxic powder and is used as an insufflation in doses of 3 to 5 grains, 30 to 60 minutes before meals; patients readily learn to inhale it into the throat through a glass tube. Cocaine and morphine should be reserved to the last stages. When the dysphagia is due to a greatly swollen epiglottis, the greatest relief is afforded by its removal under cocaine with special punch-forceps; and when the pain is caused by a tense swollen arytenoid, the removal of a piece with punch-forceps relieves tension and gives similar relief. Injection of alcohol into the superior laryngeal nerve is a useful method of alleviating pain in cases of extensive disease. Tracheotomy is seldom required, and tuberculous infection of the wound is common after this operation.

TUMOURS

INNOCENT TUMOURS

Singer's nodules are inflammatory epithelial thickenings, and may be considered as a form of pachydermia. They are found in teachers and speakers, rather than in singers, and are caused by faulty voice-production and, especially, by forcing the voice when the cords are inflamed. The appearance is that of a minute pink or whitish nodule on the edge of upper surface of the vocal cord, surrounded by a varying amount of injection; there is usually a nodule symmetrically placed on each cord, but it is frequently, larger on one side than on the other. The place where the growth occurs, and which is also the "seat of election" for other innocent tumours, is at the junction of the anterior and middle thirds of the glottis, that is, in the centre of the true vocal cord, for the posterior third of the glottis is cartilaginous. It is here that the maximum vibration occurs, and here that the cord, if swollen, comes into contact with its fellow on phonation.

Fibromata occur usually on the vocal cord on the same site as the singer's nodule, of which they are in some cases probably a development, or at the anterior commissure. They are pedunculated, smooth and round, white, pink, or brown from extravasation of blood, and vary from the size of a pin's head to that of a bean. These growths not infrequently become œdematous, when they appear translucent like a nasal polypus, and have been incorrectly described as *myxomata*.

Papillomata are reddish, papillary, pedunculated growths, and occur anywhere on the larynx, but, when single, generally occupy the "seat of election" on the vocal cord, and are seldom found on the posterior half of the glottis. Multiple papillomata occur in childhood and, as they present special characteristics, will be considered separately later.

Cysts.—A fibroma may degenerate with the formation of a cystic space in its interior. Apart from this, cysts, which may reach a large size, are found as a rarity on the upper aperture of the larynx, especially on the anterior surface of the epiglottis. They are thin-walled and translucent, with ramifying vessels running over the surface.

Angiomata occur, though rarely, on any part of the larynx either as a flat patch or a raised purple mass resembling a blackberry.

All innocent neoplasms are rather uncommon; in addition to those already mentioned, *lipomata*, *chondromata* and *thyroid-gland tumours* have been observed.

Symptoms.—A tiny growth situated on the vocal cords, or in such a situation as to prevent their approximation, causes hoarseness and a variable amount of aching and discomfort, but even a larger tumour elsewhere may cause no symptoms to attract attention. Dyspnoea results in rare cases when a neoplasm is large enough to block the air-way, but it is astonishing how slight a disturbance may be produced by a large tumour if it has grown slowly; inspiration is more difficult than expiration, except when the tumour lies below the glottis. Angiomata cause hæmorrhage, which may be slight or very severe.

Diagnosis.—This is usually easy on inspection, but a growth on the

anterior commissure, or one that drops down below the cords, may be readily overlooked. The rare tuberculoma may so exactly imitate an innocent neoplasm as to be only recognisable under the microscope. The important matter of diagnosis from a malignant neoplasm will be referred to under the latter disease.

Treatment.—Tumours situated away from the glottis and causing no symptoms should be left alone. Cysts are treated by making a large hole with punch-forceps or the cautery, for they refill after simple incision. Angiomata, especially if diffuse, are best left untouched, unless bleeding calls for interference, in which case it can usually be checked by the cautery at dull-red heat; diathermy puncture with a fine terminal through a direct laryngeal spatula, or by suspension-laryngoscopy, is a preferable method; if repeated hæmorrhage becomes a danger, the angioma can be excised by an external operation, but is usually more widely spread than appears on laryngoscopic examination. Singer's nodules, if quite small and sessile, frequently disappear under prolonged rest of the voice; the smaller nodules may be lightly touched with the galvano-cautery; larger ones should be removed with forceps. Fibromata and papillomata are removed with forceps; it causes far less disturbance to the patient if this be done under cocaine anæsthesia by the "indirect method," i.e. under guidance with the laryngeal mirror, provided that the operator has acquired the necessary skill, but since the introduction of the "direct method" they are often removed through the tube-spatula. After the little operation, absolute rest of the voice should be enjoined for a few days; in cases of singer's nodule a longer rest is necessary, with training in voice-production and avoidance of dust and conditions of vocal strain.

Multiple papillomata.—This rare but serious condition occurs almost exclusively in children and generally attracts attention between the ages of 2 and 4. The warts may be very numerous, fill the lumen with a cauliflower-like mass, and extend to the subglottic region, down the trachea and even on to the pharynx. The first symptom is hoarseness, and long-continued hoarseness in a child should suggest the possibility of papilloma; dyspnœa ensues later and becomes gradually more severe until tracheotomy is necessary. The growths may disappear after tracheotomy, or spontaneously, or after an acute illness, and tend to vanish or cease to recur about puberty. The modern treatment is to remove the growths through the tube-spatula, or by suspension-laryngoscopy, under general anæsthesia; a preliminary tracheotomy is advisable if there is much dyspnœa; several sittings may be required, and the operation must be repeated as often as the growths recur.

MALIGNANT TUMOURS

Ætiology and Pathology.—Epithelioma is by far the commonest malignant growth in the larynx, but spheroidal-cell carcinoma and sarcoma also occur. Malignant disease of the larynx proper is rare below the age of 40, and is seldom seen in women; but there is a post-cricoid epithelioma, originating on the mucous membrane of the pharynx, which is relatively common in women, and has been known to occur at such an early age as 23 or even younger. Secondary or metastatic growths are practically unknown in the larynx; on the other hand, owing to the fact that the laryngeal

lymphatics do not anastomose freely with other systems, cancers confined to the lumen of the larynx rarely become disseminated and do not readily infect the glands. Therefore, Krishaber's classification into *intrinsic* and *extrinsic* is valuable for treatment and prognosis; the former are those situated within the cavity of the larynx, while the latter affect the upper aperture, epiglottis and arytenoids, and the outer walls, such as the posterior surface of the cricoid plate.

Symptoms.—Unfortunately, intrinsic malignant tumours do not cause severe symptoms at an early stage and, particularly in hospital practice, frequently do not present themselves for treatment until they have become extrinsic by extension; hence the importance of a laryngeal examination in all patients over 40 with hoarseness which does not rapidly yield to treatment. Hoarseness is the most general, and usually the only early, symptom; owing to the deep infiltration characteristic of malignant disease, it is often more marked than the size of the tumour would appear to warrant. Cough is not a common symptom. Pain is absent in the early stages of intrinsic cancer, but is severe in the later stages and in the extrinsic forms; it radiates to the ear and side of the head, and is made worse by swallowing, speaking, and coughing. The later symptoms include involvement of the glands, fœtor of the breath, salivation, hæmorrhage, dyspnoea, dysphagia and general cachexia; often the patient dies of septic pneumonia.

On a vocal cord, epithelioma may appear as a definite tumour resembling a papilloma or angioma, or it may begin as a diffuse infiltration, or even as a mere area of thickening and congestion. On the ventricular band or posterior commissure it usually shows itself as an irregular papillary dusky-red swelling; cancer of the epiglottis ulcerates early and appears as a dirty white or reddish tumefaction. Often the only sign of a post-cricoid growth is a swollen and fixed arytenoid; sometimes the upper edge of the growth is visible, but it is frequently necessary to pass a tube-spatula, or to pull the larynx forward with a probe passed down to the glottis, before it can be inspected.

Diagnosis.—In the earliest stage the diagnosis obviously is a matter of extreme importance and sometimes one of great difficulty. The unilateral character of the infiltration is ordinarily sufficient to exclude a simple inflammatory lesion; though pachydermia may be more marked on one side, the smooth cup-shaped swelling on the vocal process is characteristic. The difficulties of diagnosis are generally between an innocent neoplasm on the one hand, and a tuberculous or syphilitic infiltration on the other. A papilloma or a fibroma on a vocal cord should be regarded with suspicion in a man over 40, and especially if, after removal, the site fails to heal promptly. An innocent neoplasm has a fine pedicle, moves freely in the air-current on phonation, there is no tumefaction at its site of origin, and it is found at or in front of the middle of the vocal cord. A malignant growth may occur in any situation; it is less movable and pedunculated, the cord in the neighbourhood is frequently swollen and may show a leash of tiny vessels running to the tumour; a white spiky appearance of the papillæ is suggestive of malignancy; a sluggish delayed movement of the cord is an important sign, insisted on by Semon, but its absence by no means excludes malignancy, for it only occurs when somewhat deep infiltration has occurred, and is absent in a considerable proportion of early cases. Epithelioma beginning as a

flat infiltration may resemble a tuberculous or syphilitic lesion, but usually other signs of these diseases are present to aid the diagnosis; in the latter the Wassermann reaction and, still more, the results of vigorous anti-syphilitic treatment will clear up the doubt. There is a form of senile tuberculosis in which infiltration of one vocal cord may closely imitate epithelioma, more especially as the pulmonary signs are merely those of bronchitis and tubercle bacilli are very scanty in the sputum. Sometimes a piece may be removed for examination, but frequently the growth is too sessile to permit it: the piece removed must not be very small, and a negative finding is of little value, for the tip of a malignant growth cannot always be distinguished microscopically from a papilloma. Biopsy should never be performed in inoperable cases, for it only stimulates the growth and does harm.

Extrinsic epithelioma is most likely to be mistaken for tertiary syphilitic ulceration. A gumma grows and ulcerates more quickly, its edge is smoother and sharper, and its base often covered by a yellow slough. Pain has little diagnostic value, for a gumma of the upper aperture may cause severe dysphagia. Palpation with the finger is of great service, for the firm hard feel of an epithelioma is very characteristic.

Treatment.—Malignant disease cannot be removed with certainty by the natural passages. Thyrotomy, or laryngo-fissure, is the operation of choice for removal of intrinsic cancer; it consists essentially in wide excision of the disease from the interior of the larynx after splitting the thyroid cartilage in the middle line. The results in suitable cases are probably better than those of removal of malignant disease in any other part of the body; there is now practically no immediate mortality in skilled hands, statistics show from 70 to 80 per cent. of permanent cures, and a useful husky voice remains. When, however, the growth has spread at all extensively to the arytenoid, or to the subglottic region, or across the anterior commissure to the opposite cord, laryngo-fissure is no longer possible and a very different picture is presented. Hemi-laryngectomy is performed in some cases in which the cancer is limited to one side, but it is impossible to protect the lungs from septic discharges and the mortality is very high. In most cases, too advanced for removal by thyrotomy, if operation is feasible, a total laryngectomy is preferable, for the trachea is sutured to the skin at the lower end of the neck and aspiration of sepsis thus avoided; in the last few years the mortality has been much reduced and the results, as regards freedom from recurrence, greatly improved. The operation leaves the patient in a condition very different from that after thyrotomy; as he breathes through the tracheal opening in the neck he cannot cough or strain and has no natural voice. Nevertheless he can often produce a fairly audible whisper by means of the air in the pharynx, or with the aid of a tube leading from the tracheotomy wound into the mouth or nose, and a number of patients succeed in passing a surprisingly happy and useful existence. Subhyoid pharyngotomy and lateral pharyngotomy are operations designed to obtain access to cancers at the upper aperture of the larynx; the latter operation gives very good results in strictly limited tumours of this region. The technique of therapy by means of X-Rays and radium has now been put on a reliable basis by determination of the appropriate dosage and by adequate screening; in many cases of malignant tumours of the larynx, great improvement can now be obtained by both these agencies, and a considerable proportion

of cures has been effected. Radium, or its emanation, is enclosed in needles or small seeds of platinum and buried, accurately spaced, in and close to the tumour; or plates containing radium are embedded in wax and applied as a collar to the neck: the two methods may be combined in the treatment of any particular case. Great care and judgment are required in the selection of cases for these various operations, and very many come under observation too late. In these much can be done by palliative treatment; careful attention to the hygiene of the mouth and teeth is of great importance, together with mild antiseptic laryngeal sprays containing hydrogen peroxide, listerine, sanitas or carbolic acid. For dysphagia, insufflations of powdered orthoform, with or without anæsthesine, is the most reliable remedy; cocaine is disappointing, for its effect is very transient and the resulting numbness interferes with swallowing; the judicious administration of morphine or heroin is eventually necessary, but the local application of these drugs is useless. Palliative tracheotomy or gastrostomy may be called for, and curettage or partial removal by knife or diathermy gives relief in some cases of cancer at the upper aperture.

PARALYSIS

Paralysis of a vocal cord is a frequent symptom of various diseases of the thorax and of the nervous system, and the laryngoscope is therefore of great value to the physician as an aid to diagnosis; this is more especially the case in that the common early form, abductor paralysis, causes no symptoms, and can only be recognised by laryngoscopic examination.

The original function of the laryngeal muscles is that of a sphincter, to prevent the entrance of fluid into the lungs, and this sphincter, or adductor, is the only muscle present in the larynx of the most primitive air-breathing animals; the abductors are a later addition, to assist the entry of air. Accordingly, in lesions of the nerve path, the abductor muscles are affected first and the primitive adductors are more resistant. But the function of phonation, much more recently acquired, is associated with adduction, and is under direct control of the will. Functional disturbances, therefore, always cause adductor paralysis, while organic lesions first affect the movement of abduction.

ORGANIC PARALYSIS

The crico-thyroid muscle is supplied by the superior laryngeal nerve, and, when this is injured, the affected cord remains slack on phonation, but, owing to the short course of the nerve, isolated paralysis of this muscle is extremely rare; it results from surgical or suicidal wounds, or by pressure from glands, but most often occurs after diphtheria. In lesions of the vagus above the origin of this branch the signs of this paralysis are obscured by that of the other muscles of the cord. The recurrent laryngeal nerves supply all the other muscles. In any progressive lesion of the nerve-path the muscles become paralysed in a definite order, the enunciation of which is known as Semon's law; the abductors are first affected, then the tensors or thyro-arytenoidei, and finally the adductors.

In *abductor paralysis* the affected cord lies in the middle line; during

phonation the sound cord adducts to meet it and the larynx appears normal, but on inspiration it is drawn outwards and backwards and appears longer than its paralysed fellow, which remains unmoved. As would be expected from the course of the recurrent nerves, the left cord is far more often affected than the right. The voice is unaltered, but, although the glottic aperture is reduced by half, there is usually dyspnoea only on exertion, except in children, in whom the narrowing of the naturally small glottis may produce sufficient obstruction to necessitate a tracheotomy.

When the thyro-arytenoid fails, the edge of the cord is concave on phonation, the cord appears narrower than its fellow, and the voice gradually becomes husky. Finally, when *total recurrent paralysis* has occurred, the cord assumes the "cadaveric position" between the middle line and the normal position of rest. On phonation, the healthy arytenoid crosses the middle line and pushes the paralysed cartilage aside; sometimes the latter drops forward and exposes its broad posterior surface, which may be mistaken for a swelling. As the cords are still able to approximate, the voice is not necessarily lost, but is hoarse and easily tired, with a characteristic breathy quality from waste of air, or a diphonic character, due to unequal vibration of the two cords.

In cases of *bilateral abductor paralysis* the cords lie together near the middle line. The voice is good, but the inability to take a full breath gives the speech a peculiar character; dyspnoea is a marked symptom accompanied by inspiratory stridor and severe paroxysmal exacerbations. When the disease progresses to complete *bilateral recurrent paralysis*, both cords remain in the cadaveric position, the dyspnoea becomes less severe but the voice is reduced to a whisper.

Diagnosis.—The diagnosis is almost entirely a matter of accurate inspection. Obliquity of the laryngoscopic image, due to faulty position of the mirror, may cause confusion. In nervous subjects the cords are sometimes adducted on inspiration, but they will abduct naturally during the involuntary inspiration which follows a prolonged phonation. The only condition which really imitates paralysis is the fixation of the arytenoid cartilage which results from disease in or around the joint; its complete immobility with the presence of swelling or scarring often aids the

1092 DISEASES OF THE RESPIRATORY SYSTEM

diagnosis, but in old-standing cases of paralysis secondary fixation frequently occurs.

Ætiology.—The ætiology is of some importance, for it is on our knowledge of their causation that the diagnostic value of these lesions depends. The movements of the cords are represented bilaterally in the cortex cerebri, and stimulation of either centre produces movement (adduction) of both cords, from which it follows that no unilateral lesion above the bulbar nuclei can paralyse the larynx, and clinically we find that it is never affected in cases of hemiplegia. The bulbar centres lie in the floor of the fourth ventricle, and here a lesion of one centre causes paralysis of the cord at the same side which, in a gradually progressive lesion, attacks first the abductor muscle. Thence the nerve fibres pass in the roots of the bulbar-accessory to the vagus and recurrent laryngeal nerve; the cause of the paralysis may, therefore, be situated (1) in the medulla, (2) at the base of the skull, (3) in the vagus, or (4) in the recurrent laryngeal nerve.

Paralyses of bulbar origin are often, but by no means always, bilateral. In lesions here and at the base of the skull neighbouring nerves are liable to be involved; thus, paralysis of a cord and of the same side of the palate may coexist (syndrome of Avellis), or paralysis of cord, palate, trapezius and sterno-mastoid from involvement of the spinal accessory roots, or persistent frequency of the pulse due to damage of the cardio-inhibitory centre or nerves. *Tabes dorsalis* is the most frequent cause of paralysis of central origin; it may affect one or both cords and may be associated with anæsthesia, paræsthesia or the spasmodic attacks called “laryngeal crises.” In general paralysis of the insane laryngeal palsy is not uncommon. It is the rule in bulbar paralysis, and is usually bilateral, but appears late in the disease. Syphilitic nuclear disease, pachymeningitis and gummata at the base of the brain are frequent causes, and here the ocular muscles, especially the external rectus, are often attacked.

Peripheral causes usually act by compression of the recurrent nerve, the most frequent being aneurysm, enlarged glands, usually tuberculous, and cancer of the œsophagus. Other causes are thyroid tumours, usually but not necessarily malignant, mediastinal tumours, cancer of the lung, pleurisy, and pulmonary tuberculosis in which the nerve, usually the right, may be involved in a lesion at the apex of the lung, or by tuberculous bronchial or tracheal glands. Neuritis is a cause of laryngeal paralysis; it may be produced by the toxins of the infectious fevers, usually diphtheria, or by organic poisons, especially lead, and more rarely arsenic and alcohol. Finally, the condition is sometimes the result of traumatism, more especially surgical operations on the thyroid gland and œsophagus.

Prognosis.—Paralysis of one cord is not in itself dangerous to life; but when the cause is undiscovered the prognosis must be guarded, for this paralysis may be for a long time the only sign of serious disease; on the other hand, the recurrent nerve may be involved in some non-progressive lesion, such as a fibrotic bronchial gland, and such cases of paralysed cord have been under observation for 20 or 30 years without change.

Treatment.—This depends on the cause. In most cases it is but a symptom of disease elsewhere and does not call for special treatment. In traumatic cases, however, the nerve may sometimes be found and sutured; afterwards, and in cases due to neuritis, strychnine and the local application

of the faradic current by means of an intra-laryngeal electrode are indicated. Tracheotomy is advisable in bilateral abductor paralysis, but a plug may usually be worn in the tube, to be removed at night and whenever dyspnoea threatens.

FUNCTIONAL PARALYSIS (FUNCTIONAL APHONIA)

Ætiology.—Functional aphonia is a common manifestation of hysteria, and has been a very frequent symptom of war-neurosis or "shell-shock," but it should be clearly stated that the majority of cases are not purely hysterical. Anything which increases the effort of phonation, such as debility or laryngeal catarrh, predisposes to this affection, which is characteristic rather of feeble neuromuscular tone than of hysteria; this explains how some women lose the voice completely with every slight cold, while other patients can produce a loud if hoarse voice with severe laryngeal disease.

Symptoms.—Paralysis of the adductors presents a totally different clinical picture from the organic paralysis. It is always bilateral; the larynx appears normal while at rest, but, on attempts at phonation, it is seen that the cords do not adduct into the position necessary for the production of the voice. Very commonly the thyro-arytenoidei are the only muscles which fail to act; the cartilaginous glottis is then properly closed, but an elliptical chink is left between the cords. If the crico-arytenoidei laterales are paretic, the entire glottis remains open to a variable extent, and, very rarely, the arytenoideus is affected alone, when a triangular aperture is left behind the vocal processes. The paralysis is hardly ever complete; indeed a considerable amount of movement is usually seen, though insufficient to produce phonation. In purely hysterical cases the onset and recovery are sudden, the cough is usually not aphonic and the voice when regained is not hoarse. In some hysterical patients there is also inability to whisper.

Treatment.—In patients suffering from debility the cause should be found and treated; chronic phthisis is such a common cause of functional aphonia that it should always be thought of in this connexion. There is frequently a slight degree of laryngitis and in some the failure of adduction is "myopathic," or due to inflammation of the muscles; in these the local condition must receive appropriate treatment. When the larynx

FIG 105.—Functional Paralysis; all during attempted phonation; V. Paresis of all the adductors; VI. Arytenoideus still active; VII. Paresis of internal tensors; VIII. Paresis of arytenoideus. (*Lancet*.)

is normal the voice can nearly always be temporarily restored by any powerful local stimulation, such as the intra-laryngeal application of chloride of zinc, or any similar drug, or of the faradic current; but the aphonia usually recurs again, and succeeding applications are less effective, so that the most difficult cases to cure are those who have had much local treatment. Far better results are obtained by moral suasion, explaining to the patient that there is no serious disease; but that he is not using his muscles correctly, and that he can produce a good voice quite easily when the laryngeal mirror or tongue-depressor is in position. With a little elementary instruction in voice-production this is usually successful, the patient's confidence is restored and the voice does not again fail; in obstinate cases some perseverance in lessons on production is required. These methods have been extraordinarily successful with gassed and shell-shocked soldiers, but it must be confessed that such certain and rapid results are not always obtainable in hysterical women.

SPASMODIC AFFECTIONS

GLOTTIC SPASM

Spasm of the laryngeal muscles produces adduction of the cords, for, though the abductors are probably affected, they are overpowered by the stronger adductor muscles.

Ætiology.—(1) In the majority of cases the spasm is a reflex set up by local irritation: foreign bodies, including the laryngoscopic mirror, irritating gases; inflammation, ulceration or tumours in or near the larynx, children being much more liable than adults to spasm from local irritation. (2) Spasm is also caused by irritation of the recurrent laryngeal nerves by enlarged glands, mediastinal tumours and, especially, by aneurysm. (3) Central nervous lesions, especially tabes. (4) Functional disturbances, frequently hysterical, often associated with globus hystericus, and sometimes excited by sexual disturbances.

Symptoms.—The attacks vary much in different subjects in severity and duration. The patient is usually aware of its onset, and clutches some support or rushes to the window. The respirations are rapid and shallow, with loud inspiratory stridor, and, in the height of a severe attack, are completely arrested with all the signs of asphyxia. The subjective sensations include a horrible feeling of anxiety, but consciousness is not lost. Many cases are less acute but persist longer, even for several hours.

Prognosis.—The attacks are practically never fatal, unless a foreign body or tumour be present.

Treatment.—During the attack amyl nitrite or chloroform may be inhaled, and ampoules of these drugs should be kept on hand. Between the attacks sources of irritation should be sought for and removed, the upper air-passages brought to a healthy condition, and the general health and mode of life should receive attention. Administration of bromides may be required when the attacks recur frequently.

LARYNGISMUS STRIDULUS

Ætiology.—This is a condition, clinically similar to glottic spasm, occurring in children. It is far commoner than the spasm of adults, and it has been suggested that the asphyxial attacks of laryngismus are caused by collapse of the soft and yielding cartilaginous framework of the larynx, and not by spasm of the muscles. It is commonest between the ages of 6 months and 2 years, but may persist later; it occurs in ill-nourished, unhealthy children, usually in association with rickets, and practically always in association with adenoids.

Symptoms.—The onset is sudden and usually at night. The child wakes gasping for breath, and a series of short noisy inspirations are followed by complete cessation of breathing and terminated by a long, crowing inspiration. There are retraction of the lower ribs and epigastrium, cyanosis and great terror and distress, and in severe cases, carpo-pedal contractions, convulsions, and evacuation of urine and fæces. When the attack is over the child is perfectly normal and there is no hoarseness. Slighter and less typical attacks often occur.

Diagnosis.—This is easy if the symptoms are carefully noted; the sudden attack of dyspnœa, with complete absence of symptoms in the intervals, is quite distinctive.

Prognosis.—The prognosis is somewhat grave in severe cases; an infant rarely dies in an attack, but is often worn out and succumbs to collapse of the lungs.

Treatment.—During the attacks the face and chest may be freely sponged with cold water, and the inhalation of amyl nitrite from a capsule broken in a handkerchief may be tried. The quickest relief can usually be obtained by drawing the tongue forward with a finger passed into the mouth to its base, a manœuvre easily performed by the mother or nurse. The attacks are so short and sharp that there is no time for a hot bath or the administration of bromides frequently recommended.

Prevention involves general tonic treatment, fresh air, wholesome food and correction of digestive disturbances. The removal of adenoids is of great importance, even if not large enough to be definitely obstructive, as is the treatment of naso-pharyngeal catarrh with the usual saline lotion which, in small children, may be dropped into the nostrils from a pipette. Bromides are to be avoided if possible as depressing, but 10 to 30 drops of liquid extract of grindelia may be given 3 or 4 times a day in milk or sweetened water as recommended by Eustace Smith.

CICATRICIAL STENOSIS

Ætiology.—Suicidal and other wounds, gunshot injuries and scalds frequently produce cicatricial narrowing of the lumen of the glottis. After thyrotomy a web may form across the anterior commissure. In the haste of an emergency tracheotomy, the wound has often been made too high and the cricoid cartilage cut through; in these cases it generally happens that, after the subsidence of the acute condition, dyspnœa follows every attempt to remove the tube, and a stenosis is found to have resulted from swelling and narrowing in the subglottic region. Similarly, a proportion of

cases intubated for diphtheria are unable to breathe without the tube, by reason of a subglottic stenosis. Lupus and tuberculosis of the larynx can produce cicatricial stenosis, and especially when the cautery has been extensively employed in treatment. Syphilis is the most fruitful cause of this condition, and the great difficulty of obtaining a cure at this stage is a powerful reason for early and thorough treatment of syphilis of the larynx. Leprosy and scleroma cause stenosis, but are rarely seen in this country. The perichondritis, which is an occasional complication of enteric fever, small-pox and diphtheria, commonly ends in severe stenosis.

Symptoms and Diagnosis.—The principal symptom is naturally dyspnoea, but in chronic cases it is remarkable how great may be the narrowing before dyspnoea becomes severe. The obstruction and the stridor are most marked on inspiration, in contra-distinction to tracheal stenosis where the stridor is both inspiratory and expiratory. The larynx moves downwards with each inspiration; this "respiratory excursion" of the larynx is a further diagnostic sign of laryngeal obstruction, but is not always present. The patient sits upright, with the head thrown back; whereas in tracheal obstruction he bends forward to relax the trachea.

Treatment.—In all cases with decided dyspnoea tracheotomy should be first performed, and in syphilitic cases it is important that all active disease should be arrested by thorough treatment before any attempt at dilatation be begun, and the stenosis itself will often be greatly improved by such treatment. The administration of iodides is dangerous in these cases, for the increased secretion is pent up behind the stenosis and may overwhelm the lungs. Difficulty in dispensing with the tube after tracheotomy is sometimes due to nervousness on the part of the child, and can then be surmounted by using a fenestrated tube which is plugged occasionally and by encouraging the patient to breathe through the mouth, by blowing soap-bubbles or sounding a whistle. When the tracheotomy wound is too high, a low tracheotomy should be performed and the original wound allowed to close; this is often sufficient to overcome the difficulty.

The successful treatment of severe cicatricial stenosis demands the greatest skill and perseverance on the part of the surgeon as well as the patient co-operation of the sufferer. The whole circumstances of the case should be carefully considered before advising difficult and prolonged treatment. Adult patients can live active lives with a permanent tracheotomy opening, which is not so serious a disability as it is generally considered to be. If the stenosis be not too extreme, a fenestrated tube may be worn which can be kept plugged during the day, so that the patient may have the use of speech and respiration by the natural passages. In children and young people a permanent tracheotomy is more harmful, and the prospect of cure by dilatation is better. The best method of dilatation is by the use of intubation tubes; under anaesthesia increasing sizes are passed until the stricture is dilated as far as possible, when the largest is left in position. This must have an especially large swell to prevent its being coughed out, or, better, is fixed by a special clamp passed through the tracheotomy fistula. In this way safety is assured, and the tube in these cases may be retained for 3 or 4 months without becoming foul; at the end of this time it is replaced, if necessary, by one of a larger size until dilatation is complete.

HAROLD S. BARWELL.

DISEASES OF THE TRACHEA

INFLAMMATION OR TRACHEITIS

. ACUTE TRACHEITIS

Acute tracheitis may occur from any condition leading to irritation of the mucous membrane of the trachea. When it occurs as a result of bacterial or chemical agency, the whole of the upper air-passages are usually involved in greater or less degree, and the clinical manifestations are not confined to the trachea. In some cases, however, the stress of the resultant reaction falls upon this tube, and the condition therefore requires separate consideration.

Ætiology.—1. *Microbic invasion.*—This is the commonest cause. The bacteria usually found associated with tracheitis are the so-called catarrhal organisms, such as the *Micrococcus catarrhalis*, the pneumococcus, the Friedländer pneumo-bacillus and Pfeiffer's *Bacillus influenzae*. Less frequently a member of the streptococcus group may be found, either alone or in association with one or more of those just mentioned. As with catarrhal inflammation of other parts of the upper air-passages, damp, cold or foggy climatic conditions predispose to tracheitis. It is more common in young and middle-aged adults than in infancy or in old age. Mouth-breathers are more liable to this condition. Exposure to sudden changes of temperature may be a factor in its onset.

Tracheitis may also occur as part of the clinical picture in some of the acute specific diseases, such as enteric fever, diphtheria, whooping-cough and measles. It is often a troublesome and distressing association or sequel of true influenza.

2. *Chemical agencies.*—Irritating or poisonous fumes and vapours may lead to a very acute form of tracheitis. It may, therefore, occur in certain occupations, unless adequate precautions are taken. The use of "poison gases" in warfare has drawn widespread attention to this form of the condition, since tracheitis was an almost constant result of certain forms of "gassing." The chief chemical irritants used in the Great War were chlorine, phosgene and yperite, or dichlorethyl sulphide, commonly known as yellow cross or mustard gas. Of these the last was perhaps the most irritant to the trachea, and fatal cases invariably showed tracheal lesions. Direct inhalation of steam may also induce an acute tracheitis.

3. *Mechanical causes.*—The presence of a foreign body, or the invasion of the trachea by extension from malignant growth in adjacent structures may lead to a local or even to a general tracheitis. It is noteworthy, however, that the trachea is frequently spared in occupations involving the respiration of dusty air, which lead to deposits in the lungs and bronchial glands with resulting pneumokonioses. Although a coal miner's lungs are black, yet his trachea may be practically normal.

Pathology.—The changes found in the trachea vary from simple catarrhal inflammation to intense destructive changes with ulceration, and in some cases croupous or membranous exudate. In the catarrhal forms, the mucous membrane shows changes similar to those in bronchitis. It is at first swollen,

red and dry, the vessels running across the trachea being engorged and clearly visible. Then, owing to increased activity of the mucous glands, excessive mucoid secretion occurs and the mucous membrane becomes moist, after which resolution may take place, or the process may proceed to a mucopurulent stage, when the fluid on the membrane coheres to form yellowish or green tenacious pellets. Occasionally numerous red blood cells are extruded and the tracheal exudate becomes streaked, tinged or uniformly pinkish.

In some inflammations, such as those induced by poison gases or inhaled steam, the mucous membrane may be intensely engorged and actual destruction may occur, involving even the deeper structures and the cartilages, so that greyish yellow sloughs result, which on separation leave ulcers. In diphtheria the characteristic false membrane composed of necrosing fibrin, leucocytes and bacilli may be found loosely attached to the mucous membrane, as in other localisations of this process. It may be primary or secondary to faucial or laryngeal diphtheria, either by direct extension or through diphtheritic infection of a tracheotomy wound.

In influenza the pink appearance of the trachea is of such constancy in fatal cases that it has come to be regarded as one of the most characteristic post-mortem changes found in this disease. The bright injection generally involves the lower half of the trachea, but it may occur along the whole length of this tube.

In whooping-cough the inflammatory reaction is usually less acute.

In typhoid fever small ulcers may occasionally be found in the trachea similar to those occurring more commonly in the larynx.

Symptoms.—Acute catarrhal tracheitis usually begins more or less acutely, like the common "cold," of which it is to be regarded as one form, with malaise, slight headache, and a mild degree of fever, the temperature being usually between 99° and 100° F., rarely 101° F. The patient soon experiences a sensation of irritation behind the sternum, rapidly leading to a harsh, dry cough of noisy character. The cough aggravates the retrosternal discomfort, which develops into a sensation of rawness or soreness, making the cough very painful and distressing. If the larynx is involved at the same time, the voice becomes hoarse and sometimes lost, or reduced to a raucous whisper. In tracheitis alone the voice is usually unaffected. After from 12 to 24 hours the condition passes into the mucoid stage. The cough becomes looser and less painful, and small pellets of tenacious mucus are coughed up, usually greyish or black in town-dwellers, whitish in those in rural conditions; in either case, the mucus may be streaked with blood or even tinged a uniform pink colour; in the more acute forms, it sometimes becomes yellow and more purulent. In the mucoid stage, the retrosternal soreness becomes less, the constitutional symptoms abate, while the temperature subsides and becomes subnormal. The patient often feels weak and out of health for some days, and is sometimes left with a noisy morning cough and tracheal irritation which may last for days or weeks. The aspect of the patient shows nothing characteristic. There is the general appearance of fever, malaise and discomfort. The rise of temperature and increase in pulse-rate are usually moderate. In the early stages physical examination of the chest shows no abnormality, but when exudation occurs a coarse wheeze may be audible over the trachea, particularly when the patient takes a deep breath or just before a cough occurs.

Diagnosis.—The association of catarrhal symptoms with a dry, harsh cough and retrosternal soreness, without signs of bronchitis, is almost pathognomonic. In some cases the diagnosis can be established with the laryngoscope or by endoscopy, but in most the discomfort which these examinations entail is unnecessary.

Prognosis.—This is almost invariably good, except in debilitated subjects or in those with cardiac or renal disease, in whom the process may spread to the larynx, bronchi or lungs. The usual course is from 2 days to a week, though cough and expectoration may persist for days or weeks. The condition may become chronic. To some extent the prognosis depends upon the care and treatment in the initial stage. Cases that are neglected are liable to become chronic.

Treatment.—The prophylactic and remedial treatment of acute tracheitis is practically identical with that of acute bronchitis of the larger tubes. Even in mild cases the patient should go to bed, though this may be necessary only for 1 or 2 days; but he should keep to his room till his temperature has become normal. There may be less need for expectorants than in bronchitis, and a simple saline diaphoretic mixture, with the addition later of *tinct. ipecac.* and *tinct. opii camphorata*, may be all that is necessary. Sedative inhalations, such as vapor benzoini, are specially useful, and counter-irritation to the sternal region is comforting and grateful to the patient. When a chronic noisy cough develops, a mixture containing small doses of apomorphine and *tinct. chloroform. et morphin. co.* often gives relief.

When tracheitis occurs as part of some specific disease, such as diphtheria or influenza, the treatment should be that appropriate to the primary disease.

In "gassing," every effort should be made to relieve the distressing and painful symptoms, and for this purpose morphine, either alone or in combination with atropine and strychnine, may be required. Various inhalations may be tried, and useless cough should be checked by sedative mixtures or by a linctus of heroin, morphine or codeine.

CHRONIC TRACHEITIS

Ætiology.—Chronic tracheitis may follow an acute attack, or it may develop insidiously in patients suffering from chronic laryngitis or bronchitis. Inhalation of cigarette smoke is a not infrequent cause. It is also sometimes a sequel of chronic rhinitis, especially with the atrophic form or *ozæna*. A certain degree of chronic tracheitis accompanies the specific lesions of syphilis and tuberculosis, which are described below.

Pathology.—Various degrees of chronic inflammatory lesions may be found. In chronic catarrhal tracheitis, the vessels are distended or engorged, and the mucous membrane of the trachea becomes thickened and more or less covered with mucoid or muco-purulent secretion, the histological changes being those of chronic catarrhal inflammation, namely, shedding of the ciliated epithelial cells, overactivity of the mucous glands, and sometimes thickening and induration of the submucous tissues from proliferative changes. A condition of perichondritis of the tracheal cartilages may, in this case, be observed, and this may result in a mammillated appearance in the internal aspect of the trachea. In *ozæna*, crusts similar to those in the nose and pharynx may form on the tracheal mucosa.

1100 DISEASES OF THE RESPIRATORY SYSTEM

Symptoms.—The symptoms of chronic tracheitis are similar to those of the acute form. There is a sense of discomfort and irritation about the trachea and a chronic, almost dry cough, often worse in the morning. There is generally some scanty, sticky expectoration, mucoid or muco-purulent, darkened by carbon particles and occasionally blood-tinged.

There are practically no physical signs of this condition, except that the tracheal changes can be observed by the laryngoscope or by endoscopy of the trachea.

Diagnosis.—This is concerned chiefly with its differentiation from chronic changes in the trachea due to syphilis, tuberculosis or leprosy and to the effects of new growths. It must largely be made by endoscopic examination.

Prognosis.—The prognosis depends upon the cause. When this can be removed, as by treatment of predisposing conditions in the nose and throat, the outlook is good. When the tracheitis is due to other conditions, such as syphilis and tuberculosis, it depends upon the situation and extent of the other lesions and upon the treatment adopted.

Treatment.—This is, in its main features, similar to that of acute tracheitis, but climatic treatment may be of great importance. The patient may perhaps spend the winter months in a warm or equable and clear climate with great advantage. Vaccine treatment may also yield good results. When other conditions are concerned, such as *ozæna*, syphilis or tuberculosis, the treatment appropriate to them should be employed as well.

CYSTS AND TUMOURS

These are rare conditions, but require careful consideration.

CYSTS

Owing to weakening of the wall of the trachea, local bulging may occur, giving rise to a cystic, air-containing swelling in the neck, in direct communication with the lumen of the trachea. Such cysts are known as "tracheoceles" or "aeroceles." They are resonant to percussion and can often be temporarily reduced by pressure.

Small retention cysts may occur in the posterior wall of the trachea, from obstruction of the ducts of the mucous glands as they pass through the trachealis muscle. They are of pathological interest only, and do not give rise to symptoms.

SIMPLE TUMOURS

The most important is papilloma. It occurs chiefly in children and is usually pedunculated. When it grows in polypoid form it may lead to obstruction of the trachea low down, in which case tracheotomy may fail to give relief, and death results unless the tumour can be removed by endoscopic methods.

Other innocent tumours occur, but are rare. They include enchondrosis from localised overgrowth of cartilage, multiple enchondromata, and osteoma from ossification of a pre-existing enchondroma. Lipoma and aberrant thyroid tumours may occur, but are very rare.

Symptoms.—These tumours produce varying degrees of tracheal obstruction, and can usually only be recognised by endoscopy. Treatment is considered under that of tracheal obstruction.

MALIGNANT TUMOURS

A few cases of primary carcinoma of the trachea have been recorded. Secondary growths are not common, but the trachea is often involved and infiltrated by primary carcinoma in adjacent structures, such as the oesophagus, the thyroid, the larynx, or by the extension of secondary deposits in the cervical or mediastinal glands.

Primary sarcoma of the trachea is also very rare. The growth is usually smooth and not pedunculated. Secondary deposits of sarcoma in the trachea may occur from sarcoma of distant organs, such as the kidney; or it may be invaded directly by sarcoma originating in the thymus or other mediastinal structures, and especially by lympho-sarcoma of the mediastinal glands.

Symptoms.—The tracheal symptoms and signs are usually those of obstruction, accompanied by pain. When the primary growth is in the oesophagus, antecedent dysphagia and sometimes laryngeal paralysis reveal the origin of the tracheal symptoms when they occur. In this case, copious frothy mucoid expectoration is frequent, and when ulceration develops, food particles may enter the trachea, excite cough and soon lead to inhalation broncho-pneumonia or gangrene. When the growth is near the bifurcation, urgent dyspnoea is the rule, and spasmodic attacks may occur, causing the most extreme distress. In most cases of tracheal growth the characteristic clanging brassy cough (gander cough) of tracheal obstruction can be heard. The trachea may be pushed to one side and its lumen distorted and obstructed by growth in the cervical glands. In mediastinal new-growth invading the trachea, the pressure signs and symptoms characteristic of that disease usually render the explanation of the tracheal symptoms apparent.

Course.—This is generally rapidly progressive.

Diagnosis.—Intratracheal growths have to be differentiated from other causes of tracheal obstruction and the diagnosis is considered in detail under that condition. Endoscopy would afford valuable confirmation if it is practicable or desirable. In oesophageal and mediastinal new-growths invading the trachea, X-Ray examination may assist in diagnosis.

Prognosis.—This is hopeless, death occurring from asphyxia or from some complication or by asthenia.

Treatment.—Treatment can be palliative and symptomatic only. In obstruction, it may be possible in rare cases to give temporary relief by a low tracheotomy, but as a rule this is impossible, owing to the presence of obstruction below any point where the trachea is accessible.

THE INFECTIVE GRANULOMATA

SYPHILIS

The trachea may be affected in both the congenital and acquired forms. In congenital syphilis, a progressive cicatrisation may occur, leading to

stenosis. In acquired syphilis, during the secondary stage, the mucous membrane of the trachea may become generally hyperæmic, or small raised mucus patches may develop locally. In the tertiary period, gummata may occur in the trachea, the commonest site being towards the lower end. Degenerative processes, leading to necrosis and softening, eventually result in ulceration, sometimes with local sloughing of parts of the tracheal rings. In the process of cicatrisation a progressive stenosis may develop.

Symptoms.—Symptoms are those of chronic tracheitis and tracheal irritation in both the secondary and tertiary manifestations, but in the latter, signs of tracheal stenosis may develop when scarring and healing are in progress. Laryngeal involvement occurring at the same time tends to distract attention from the tracheal lesions or to obscure them.

Diagnosis.—The diagnosis of syphilis of the trachea depends upon a careful study of the history of the case, indications of tracheal irritation, laryngoscopic or endoscopic examination, the coexistence of other manifestations of syphilis, and in their absence, a positive Wassermann reaction.

Prognosis.—If the condition is recognised early, excellent results may be obtained by treatment, but it is obvious that where deep destructive changes have resulted, medicinal measures can only palliate.

Treatment.—Anti-syphilitic treatment should be administered vigorously, and after a course of neo-salvarsan or novarsenobillon, mercury should be given. Inunction seems sometimes of special value in such cases. In cases of stenosis of the trachea from cicatrisation, dilatation of the stricture by means of bougies introduced through an endoscope may be practicable and afford useful help.

TUBERCULOSIS

Tuberculosis of the trachea is occasionally found post mortem in advanced cases of pulmonary tuberculosis, usually in those with extensive laryngeal involvement. Primary tracheal tuberculosis is unknown. The rarity even of secondary lesions in this tube is probably to be explained by the ciliated epithelium preventing lodgment of the bacilli.

Pathology.—Tuberculous lesions may occur at any part of the trachea, but they are more frequent in the lower part and on the posterior wall. When they occur they are usually numerous. There may be some general hyperæmia, or small tubercles, varying in size from a pin's head to a split pea, may be visible. Later, superficial ulceration occurs, forming irregular punched-out ulcers. Occasionally, the process may extend deeper, and erosion of the cartilages may occur, with the formation of sinuses and even fistulous communication with the œsophagus.

Symptoms.—Since tracheal tuberculosis is usually a late manifestation of advanced disease, its clinical indications are slight and are usually obscured by the more obvious laryngeal and pulmonary symptoms and signs, though if the process extends deeply and produces sinuses and fistulous tracks, it may become apparent. The actual tracheal symptoms are those of cough and retrosternal soreness.

Diagnosis.—This condition has to be distinguished from other chronic tracheal lesions, and a diagnosis can only be made from a careful review of the history, the general evidence of tuberculous disease and by the tracheal involvement which may be visible by endoscopy.

Treatment.—This must, from the nature of things, be largely palliative, and is in effect practically identical with that of laryngeal tuberculosis, notably intratracheal insufflation with orthoform and anæsthesine.

LEPROSY

In some cases of this disease, granulomatous lesions occur in the trachea, and these may eventually give rise to tracheal stenosis, owing to the contraction of new-formed fibrous tissue. The diagnosis can only be made from the occurrence of tracheal symptoms in a case with established lesions of leprosy in other parts.

The treatment is symptomatic.

SCLEROMA

Although in most cases this condition affects the nose only, scleromatous lesions may be found in the trachea as a pathological curiosity. The disease in any form is rare in England, and occurs chiefly in Poland and Austria. The nodules of granulomatous tissue in the trachea may cause partial obstruction mechanically, or, on contraction, lead to actual stenosis.

TRACHEAL OBSTRUCTION

Obstruction to the lumen of the trachea may be produced by foreign bodies, by conditions originating in the trachea, and by pressure from without.

FOREIGN BODIES IN THE TRACHEA

The commonest route by which foreign bodies enter the trachea is through the mouth and larynx, in the acts of breathing, laughing, yawning, sighing, or before and after coughing, when food or some foreign substance is in the mouth. A piece of bone, a stud, button, false teeth, chewing gum, peas, articles of food, nuts, grains of wheat, beads or blades of grass are among the substances which may gain entrance to the trachea in this manner. Surgical operations in the mouth and throat may lead to the inhalation of a tooth, a piece of tonsil or a mass of adenoid tissue. Material vomited from the stomach, such as food, blood clot or intestinal worms, may be inhaled into the trachea. A large blood clot in hæmoptysis may temporarily obstruct it. Foreign bodies may also gain access through the tracheal wall, such as small projectiles in wounds of the neck, a piece of new growth, or tuberculous glands by ulceration through the wall.

Unless it becomes impacted, or is too large to enter one of the two main bronchi, a foreign body rarely remains long in the trachea. It either causes death with dramatic rapidity, is coughed out again, or passes down into one or other of the large bronchi or their secondary divisions, where it produces results which are described in the section on diseases of the bronchi.

Symptoms.—These depend upon the mode of entry, the size of the foreign body, and the degree of obstruction to the air current which it induces, but in general the tracheal symptoms are less urgent than those of laryngeal obstruction, and less serious than those of obstruction of one or other main bronchus. There may be intense dyspnoea, with great discomfort and alarm

during the actual passage through the larynx of a small foreign body, especially if it is temporarily arrested there; but when it enters the trachea there is an almost instantaneous cessation of the acute distress, though some degree of dyspnoea may persist. The type of dyspnoea is inspiratory in the main, though a minor degree of expiratory difficulty may be apparent if the foreign body is of considerable size. There may be a definite stridor with both phases of respiration, but it is more pronounced in inspiration. If the foreign body remains loose in the trachea, which may occur if it is rounded and too large to engage in one of the main bronchial divisions, a sound of vibratory character may be heard on auscultation of the trachea, sometimes described as the *bruit de grelottement*. This may be produced by friction of the foreign body against the tracheal wall, or more commonly by the air passing over it during respiration. A paroxysmal cough may occur, caused by the foreign body irritating the sensitive posterior wall of the trachea, and during such an attack the foreign body may be forced up to the larynx, obstruct it, or cause reflex spasm with intense dyspnoea and cyanosis and a risk of suffocation, unless it drops back, is coughed out, or removed. When sudden rupture of caseous material into the trachea occurs, the lumen may be blocked and death take place rapidly.

Course.—A foreign body impacted in the trachea may give rise to septic inflammation of its walls, with subsequent cicatrization after removal, or it may lead to secondary infective processes in the lungs, such as purulent bronchitis and broncho-pneumonia.

Diagnosis.—The history of disappearance of some object from the mouth during coughing, breathing or laughing should give rise to suspicion of an inhaled foreign body, and this may be confirmed by seeing the object directly by endoscopy, or indirectly by means of the X-Rays.

Prognosis.—This depends in the main on the nature of the foreign body, and the time elapsing before its removal. An irregular, rough or soft foreign body is more likely to induce septic complications than a smooth, hard substance. Apart from rapidly fatal results, the prognosis is better with intratracheal foreign bodies than with those reaching the bronchi. If removal is effected within 24 to 36 hours, recovery is usually rapid and complete.

Treatment.—Treatment consists in rapid removal with as little damage to the trachea and larynx as possible. This may be effected by means of forceps passed through a bronchoscope, a method requiring expert manipulation, or by tracheotomy alone, when the foreign body may be coughed out through the opening or be easily removed by forceps. The tracheotomy wound should be kept open by means of a dilator instead of the usual tracheotomy tube. Inversion of the patient in the hope that gravity may assist the expiratory efforts of cough is dangerous and should only be attempted after tracheotomy has been performed. Where rupture of a caseous gland or softening newgrowth occurs into the trachea, an immediate tracheotomy may be necessary.

OBSTRUCTION FROM CICATRISATION OF THE TRACHEAL WALLS

Ætiology.—This may result from any condition leading to ulceration of the tracheal walls, with subsequent healing, such as a syphilitic gumma,

or less commonly other granulomata, such as tubercle, leprosy or scleroma. Another cause is cicatrisation from wounds of the trachea, accidental, suicidal or after tracheotomy, when the incision has been made too near the cricoid, or when the wound has become infected or the tube left in too long. Scarring from damage to the trachea by the inhalation of boiling or caustic liquids or even by inhaled gases may lead to stenosis.

Pathology.—The deformity of the trachea and the obstruction of its lumen depend upon the situation and the extent of the cicatricial contraction of its walls. It may be local, producing an hour-glass constriction, or involve a long extent of the tube. Occasionally, especially in syphilitic lesions stenosis may occur at two different levels.

Symptoms.—These depend upon the degree of stenosis, the rapidity with which it develops, and the condition of the larynx, bronchi and lungs. When the stenosis is produced gradually, as in cicatrisation, a degree of obstruction may result, greater than would be compatible with life if suddenly induced. In the early stages of a progressive stenosis, slight dyspnoea may be present on exertion, and during sleep a faint stridor may be audible, disappearing when the patient is awake. As the contraction progresses, the dyspnoea becomes more marked, and a definite and persistent stridor develops, at first inspiratory only, though expiration may become both noisy and obstructed. The patient may experience a sensation of obstruction referred to the neck or under the sternum, accompanied by pain and irritation, leading to cough, which may be dry, noisy and metallic, or accompanied by more or less frothy sputum, if the primary condition is associated with widespread tracheitis. The voice may lose tone and volume, and the patient talk more quietly than normal and with some evident effort. In advancing stenosis, sudden and alarming attacks of dyspnoea may occur, leading to cyanosis and threatening suffocation. These attacks are usually due to an accumulation of mucus at the site of the stenosis. The patient in advancing degrees of obstruction cannot lie down, and generally sits leaning forward with chin depressed. It may be noted that the extraordinary muscles of respiration contract forcibly, and yet the laryngeal excursions may be small or hardly noticeable, in contrast with those of laryngeal obstruction in which they are maximal. This distinguishing sign was first pointed out by Gerhardt, and is of value, but unfortunately it is not absolute and cannot, therefore, be regarded as pathognomonic. On auscultation over the trachea, a noisy roar may be audible, of maximum intensity near to the obstruction, whereas the breath sounds over both lungs may be deficient, although the stridor may be conducted bilaterally.

Course.—The course of cicatricial stenosis is usually progressive, unless arrested by treatment, and the dyspnoeic attacks become more frequent and alarming.

Diagnosis.—Tracheal obstruction from cicatrisation has to be distinguished from laryngeal obstruction, in which the symptoms are usually more acute and more urgent. Gerhardt's sign described above may also be suggestive. It may also be differentiated from obstruction due to pressure from without (*vide infra*). The only reliable method of distinction is by direct inspection with the bronchoscope.

Prognosis.—Early syphilitic stenosis may be arrested by appropriate anti-syphilitic treatment. Obstruction due to other granulomatous con-

ditions varies with the severity and extent of the primary lesions. Caseous material or degenerated growth ulcerating into the trachea is usually immediately fatal, or leads to death within a few days from pulmonary complications.

Treatment.—Rest, avoidance of exertion, smoking and alcohol should be advised. The patient's fears should be allayed and symptomatic treatment ordered, such as sedative inhalations or a linctus to check useless cough. In syphilitic stenosis vigorous anti-syphilitic treatment with salvarsan¹ should be given. A low tracheotomy may be necessary for an intractable stricture high up in the trachea. In some cases where an ordinary tracheotomy cannot be performed below the stricture, it may be possible to insert Koenig's long tracheotomy tube through an opening in the trachea made above it. In other cases, dilatation of a fibrous stricture by bougies passed through an endoscope may be feasible.

OBSTRUCTION FROM EXTERNAL PRESSURE

Pressure on the trachea may occur in the neck or in the mediastinum.

Causes of pressure in the neck.—Strangulation, throttling or garotting leads to death by occlusion of the trachea and suffocation. Enlargement of both lobes of the thyroid body may cause lateral compression of the trachea, until eventually its lumen is reduced to a narrow slit—the so-called “scabbard trachea.” Irregular or unilateral enlargements on the other hand cause deviation of the trachea, with kinking of its lumen. Other less common causes of compression of the trachea are enlargement of the cervical glands from tuberculosis, malignant disease, Hodgkin's disease or leukaemia. The trachea may be pressed on from behind by a foreign body impacted in the oesophagus, or by a bony tumour arising from the vertebræ.

Causes of pressure in the mediastinum.—An aneurysm of the aortic arch may press directly upon the trachea at, or near, the bifurcation and cause obstruction. Similarly deep pressure may be caused by a retrosternal goitre, a persistent and enlarged thymus, or a thymic abscess, mediastinal glands enlarged from any cause, usually malignant disease, a dermoid cyst or a bony tumour originating in the sternum.

Symptoms.—The symptoms are in the main identical with those of stenosis of the trachea from intrinsic causes, with the special symptoms due to the primary external condition superadded.

Diagnosis.—This may be simple and obvious, as in those cases due to pressure from tumours in the neck, whereas, in those due to mediastinal pressure, it is usually only possible after a careful survey of all the symptoms, and is in brief identical with that of aneurysm or mediastinal new-growth, to which reference should be made. In some cases X-Ray examination may give valuable information.

Prognosis.—This is good in obstruction due to causes in the neck other than malignant disease, but it is almost uniformly bad, indeed hopeless, in obstruction due to mediastinal causes, with the exception of abscess and some thymic conditions.

¹ According to Mr. Harold Barwell, administration of potassium iodide is very dangerous, as it increases the secretion which is pent up behind the stenosis. It may be given in combination with belladonna, but it is better withheld until the severity of the condition has been relieved by salvarsan.

Treatment.—The treatment is that of the primary condition. In goitre and tuberculous glands, in simple tumours and some thymic conditions, operation may be possible and may effect complete cure. In those due to mediastinal pressure, especially from aneurysm or new-growth, treatment, in most cases, can be only palliative or symptomatic, and directed to the relief of pain, dyspnœa, cough and distress.

INJURY

Direct violence to the trachea has been known to cause rupture when the chin is raised upwards and the trachea is, therefore, extended.

R. A. YOUNG.

G. E. BEAUMONT.

DISEASES OF THE BRONCHI

BRONCHITIS

Inflammation of the bronchi, or bronchitis, is one of the commonest maladies and may be induced by a variety of causes. These, in the main, fall into three groups, bacterial, chemical and mechanical, similar to the causes of tracheitis, which is, indeed, in many cases, a concomitant or antecedent of bronchitis, so that tracheo-bronchitis would be a more accurate designation of the majority of cases. At the same time it should be recognised that the trachea may be alone or predominantly affected, while, on the other hand, in many cases of bronchitis of the smaller tubes, the trachea may escape, or be only slightly involved.

Bronchitis is so varied in its extent and in the form and severity of its manifestations that a satisfactory classification is somewhat difficult to formulate. Fowler's classification into (1) acute bronchitis, (*a*) of the larger tubes, and (*b*) of the smaller tubes; (2) chronic bronchitis; (3) secondary bronchitis; and (4) plastic or fibrinous bronchitis, is convenient as a combined clinical and pathological grouping, but fails to separate what appear to be clinically distinct entities. We propose to consider the clinical manifestations of bronchitis according to the following classification:

1. ACUTE FORMS—(*a*) Catarrhal bronchitis, (1) of the larger tubes, (2) of the smaller tubes; (*b*) suppurative; (*c*) secondary bronchitis; (*d*) bronchitis due to mechanical and chemical agencies; (*e*) fibrinous.

2. CHRONIC FORMS—(*a*) Catarrhal, (*b*) suppurative, (*c*) secondary, (*d*) due to mechanical agencies, and (*e*) fibrinous.

ACUTE BRONCHITIS

ACUTE CATARRHAL BRONCHITIS OF THE LARGER TUBES

Synonyms.—This condition is often called Bronchial Catarrh, or Acute Tracheo-bronchitis.

Ætiology.—*Predisposing causes.*—Climate and latitude undoubtedly

play an important part. Catarrhal bronchitis is rare in polar and arctic regions and near the equator, but is very prevalent in damp and foggy climates. In England attacks are common in late autumn, winter and early spring. It is probable that some degree of hereditary predisposition occurs, since "weakness of the chest" is common in some families. Owing chiefly to greater exposure, the disease occurs more frequently in men than in women. It is most common at the extremes of life, infancy and old age, but it is not infrequent at any age. Fatigue and privation play their part, and exposure to cold, wet or fog so frequently seems to initiate the attack that it is often regarded as the exciting cause. Scoliosis, kypho-scoliosis and other malformations or deformities of the chest predispose to bronchitis, and some of them are induced or aggravated by bronchitis early in life. Chronic cardiac and renal disease both render their subjects more liable to bronchitis, as do also conditions of the nose and pharynx which lead to mouth-breathing, in consequence of the inhalation of air which is unwarmed and unfiltered by the nose. In childhood, dentition seems to be a frequent predisposing condition.

The exciting cause is usually one of the catarrh-producing organisms, and one or more of the following may be found in the sputum: the pneumococcus, Friedländer's pneumo-bacillus, streptococci, *Micrococcus catarrhalis*, staphylococci, *M. tetragenus*, and occasionally *Bacillus coli communis*. It may also be caused by the *Spirochæta bronchialis*. In health, the bronchial mucosa is in all probability sterile, though this has been disputed, and it is possible that a "carrier" condition may occur here as in the upper air-passages.

Pathology.—The changes induced in the bronchi are similar to those in the nasal mucosa in coryza and in the trachea in tracheitis. Three stages may be described: An initial dry stage, when there is active hyperæmia of the bronchial mucosa, with exudation into the submucous layer, causing temporary diminution of the bronchial secretion from occlusion of the mucous ducts. The second or mucoid stage is associated with copious discharge of mucoid secretion, owing to increased activity of the mucous glands, this secretion being mixed with shed ciliated epithelial cells and scanty leucocytes. Sometimes in acute cases a few red blood corpuscles are present. The third stage is that of resolution, though not infrequently a muco-purulent stage occurs, when the sputum becomes less copious and greenish in colour from large numbers of pus cells.

In fatal cases the lung tissue may appear slightly distended and red, while the bases may be sodden from œdema. On section, the bronchi appear injected and the mucosa is swollen. On squeezing the lung, beads of mucoid fluid or muco-pus exude from the cut ends of the bronchi. There is no consolidation and the lung tissue floats in water.

Symptoms.—An attack of acute bronchitis generally begins suddenly, with malaise, aching in the limbs, and a sense of oppression in the chest. If the trachea is also involved, there is the characteristic feeling of rawness under the sternum. The temperature rises, varying from 99° to 100° F. in mild cases to 103° F. in more severe ones. The cough is at first dry, irritating and ineffective, but in a few hours it becomes looser. The sputum in the early stage is scanty, tenacious and sometimes streaked with blood; it then becomes copious, mucoid and frothy in character, and is found to

contain mucus, shed epithelial cells, leucocytes and red blood corpuscles later it lessens in quantity and may become thick, yellow and muco-purulent. With the onset of expectoration there is generally an abatement in the symptoms, the rawness under the sternum disappears, and the feeling of pain or soreness about the pectoral muscles and the costal attachments of the diaphragm lessens. The febrile reaction may last only 3 or 4 days, but the cough and expectoration may go on for 10 days or longer, gradually diminishing, until they are present only night and morning, and then cease completely.

In the early stage the patient is flushed and the breathing may be slightly increased in rate, but it is rarely or never laboured, unless emphysema co-exists. Vocal fremitus is unaltered, but rhonchal fremitus may sometimes be felt over one lung or both. The chief physical signs are discovered only on auscultation. The breath sounds may be harsher and higher-pitched, particularly in infants and children, but they remain vesicular, and expiration may be prolonged. The voice conduction is unaltered. As a rule rhonchi, either sonorous or sibilant, according to the size of the bronchus in which they are produced, are audible over both lungs and during the mucoid stage bubbling râles may be heard, especially at the bases.

Complications and Sequelæ.—Bronchitis may go on to bronchopneumonia or may be followed by lobar pneumonia, fibroid induration or bronchiectasis. It may lead to chronic bronchitis, or be followed by active tuberculosis. Occasionally acute interstitial emphysema may result from violent coughing.

Course.—This is variable. The patient may be convalescent in from 7 to 14 days, but cough, expectoration and a condition of debility may continue for several weeks, though, in this case, the possibility of pulmonary tuberculosis should always be considered.

Diagnosis.—The diagnosis of bronchitis is usually easy, owing to the characteristic rhonchi, but it is important to differentiate primary bronchitis from bronchitis occurring as a secondary condition in acute specific fevers and other diseases.

Prognosis.—Bronchitis of the larger tubes is rarely fatal, except when it occurs in infants or the aged, or as a complication of advanced cardiac or renal disease.

Treatment.—*Prophylactic.*—This consists in the avoidance of stuffy, ill-ventilated rooms and places of entertainment when catarrhal infections are rife. In mouth-breathers, steps should be taken to deal with the conditions of the naso-pharynx inducing this habit, and instruction in normal breathing given. In dusty occupations, suitable measures should be taken to minimise the irritant particles in the air, as is now done in most factories and workshops. Where poisonous gases have to be encountered the excellent form of gas-mask evolved during the war should be utilised.

Prophylactic inoculation by vaccines, either from stock mixtures such as are now available, or from autogenous cultures, are now being extensively used, and with some success. Detoxicated vaccines are also used for this purpose, so that larger doses can be administered. An autogenous vaccine is usually to be preferred, if possible. The dose given depends upon the organism and varies from 1 to 50 or 100 millions. Two or three doses at intervals of 7 to 10 to 14 days are usually given in the case of the stock.

1110 DISEASES OF THE RESPIRATORY SYSTEM

vaccines, whereas with the autogenous a course of 6 to 12 gradually increasing doses is given at intervals of about a week.

General.—No matter how mild the attack may be at the onset, the patient should be kept in bed. This may only be necessary for 1 or 2 days, but he should keep to his room till his temperature has returned to normal. The Turkish bath taken by some patients at the first onset is unwise and should be discouraged. The room temperature should be kept at 60° to 65° F. While the temperature is raised the diet should be the ordinary, simple, liquid diet suitable to febrile conditions, namely, milk, weak tea, cocoa and simple gruels, broths or one of the many invalid foods. The patient is often thirsty, and warm or hot demulcent drinks, such as toast water, fruit juices in hot water, and linseed tea sometimes afford great comfort. The air of the bedroom may be moistened by means of a steam kettle in the dry stage, but the use of a steam tent is to be avoided. Local applications over the sternum, acting as counter-irritants, seem to give some relief to the distressing soreness so often complained of. A mustard leaf or one of the medicated wools is the most easy to apply, but a linseed poultice, anti-phlogistine or a liniment, such as camphorated oil or the acetic turpentine liniment, may be ordered. Some patients find a cold or hot compress to the neck comforting. Medicated inhalations may be used, either in a special inhaler or in a domestic substitute, such as a jug. At first vapor benzoini—1 drachm to the pint—is the most comforting, but in later stages vapor pini (*olei pini sibericæ*, ℥ x.; *mag. carb. levis*, gr. x; *aquam ad 3ij*)—2 drachms to the pint—or a dry inhalation of creosote, terebene and spirits of chloroform may be useful. It is often wise to start treatment with an aperient, unless this is contra-indicated. In the dry stage, a simple saline diaphoretic mixture may be given, with *tinct. ipecacuanhæ* or *vin. antimonialis* in small doses. One-drop doses of tincture of aconite are also sometimes given. When expectoration starts it may be encouraged by saline and stimulating expectorants, such as ammonium chloride and carbonate, combined with squills and flavoured with syrup of tolu or of Virginian prune. For the first night it may be well to give 10 grains of Dover's powder to relieve discomfort and secure sleep.

During convalescence the patient should take care to avoid chill and should be given a more liberal diet. A mixture of strychnine and phosphoric acid may be given for a few days, and a linctus or lozenge containing small doses of heroin or other sedative, to lessen the ineffective cough, which not infrequently occurs. Convalescence is usually shortened by a few days' stay at the coast, especially the south.

When bronchitis occurs as a part of some specific disease, such as diphtheria or influenza, the treatment should be that appropriate to the particular disease.

ACUTE CATARRHAL BRONCHITIS OF THE SMALLER TUBES

Synonym.—Capillary Bronchitis.

It is open to question whether this condition exists as a separate entity. When the finer bronchi and bronchioles are inflamed the alveoli invariably become involved, since very little swelling of the bronchiolar walls is sufficient to occlude the lumen of the tube, with the inevitable production of an area

of lobular collapse. The transition from this condition to actual lobular pneumonia is a very small one. In any case, the causes, the symptoms and the treatment of capillary bronchitis and broncho-pneumonia are identical. (See Secondary Broncho-pneumonia.)

ACUTE SUPPURATIVE BRONCHITIS

Synonyms.—Sometimes called Acute Purulent Bronchitis, or Suffocative Catarrh.

This condition was brought into prominence during the Great War. In 1916 and 1917 it appeared in epidemic form amongst the British troops in England and France. Although it was then regarded by some observers as a new disease, it is more probable that it was, in reality, an epidemic form of a condition usually rare and sporadic and previously termed "suffocative catarrh." That name has unfortunately been applied loosely to a number of conditions associated with acute dyspnoea.

Ætiology.—*Predisposing causes.*—The exceptionally severe winter of 1916-17, together with conditions of overcrowding in huts and billets, were undoubtedly concerned in the epidemic just mentioned. The condition affects young adults chiefly, and is much more common in men. Over-exertion, fatigue and debility predispose to it, but the disease may occur in robust and healthy persons. A history of chill may be given, but often no obvious cause can be discovered.

Exciting cause.—The organisms usually found are the pneumococcus and Pfeiffer's *Bacillus influenzae*, the latter being reported in 90 per cent. in some series of cases. The *Micrococcus catarrhalis* is also sometimes present.

Pathology.—A very intense inflammation occurs in the medium-sized and small bronchi, leading to an exudate rich in leucocytes. The inflammatory process may extend to the alveoli, which then contain a fibrinous fluid, with entangled red cells. The condition occurs in both lungs and is usually almost universal, no portion being spared. Post mortem the lungs are heavy and red in colour. On section the bronchi are found to contain a thick yellow purulent fluid. Small areas of collapse and sometimes of broncho-pneumonic consolidation are seen, and there is usually œdema of the bases. Plastic pleurisy is not infrequent, and the glands at the root of the lung are enlarged.

Symptoms.—The onset is usually abrupt, often in young people apparently in robust health. A definite chill may occur, or only coryza and general malaise, with aching of the muscles. The temperature rises quickly and may reach 104° F. early in the disease. A cough soon develops and extreme dyspnoea is a characteristic feature. Expectoration starts early, often on the second or third day. At first it may be streaked with blood, but it soon becomes yellowish green and nummular; it consists of almost pure pus; there is often as much as 5 or 6 ounces in 24 hours. In most instances there is great prostration. In grave cases the patient becomes unconscious and loses control of the sphincters.

There is intense cyanosis, the face, lips and ears being purple. Respiration is rapid, 30 or 40 per minute, and the accessory muscles are often in full action. Palpation and percussion may not show any abnormality, though slight dullness is sometimes present at the bases. At first no

1112 DISEASES OF THE RESPIRATORY SYSTEM

signs may be discovered on auscultation, but soon the breath sounds become largely obscured by medium-sized bubbling râles, often audible from apex to base, both front and back. The pulse is frequent, the right heart may dilate and the heart-sounds become weak.

Complications and Sequelæ.—In severe cases recurrent bronchitis, broncho-pneumonia, fibroid disease or emphysema may follow.

Course.—In favourable cases complete restoration to health results. In severe cases the course is rapid, the patient becomes comatose from toxæmia, expectoration ceases and death occurs from exhaustion in 2 or 3 days from the onset. In other cases the disease may last for weeks and proceed to recovery or death.

Diagnosis.—The early occurrence of marked dyspnœa and cyanosis, the expectoration of copious pus, and the widespread râles without dullness are very suggestive of acute suppurative bronchitis. The disease must be differentiated from other conditions described as acute suffocative catarrh, that are associated with extreme dyspnœa and cyanosis.

Acute pulmonary œdema is usually afebrile, and the sputum is albuminous, frothy and copious. The condition leading to it, such as cardiac or renal disease, may be apparent.

Capillary bronchitis or broncho-pneumonia may give rise to difficulty, but in these conditions the sputum is scanty, tenacious, sometimes rusty, and but rarely purulent; moreover, cyanosis and dyspnœa develop late and depend upon the extent of the disease and the condition of the right side of the heart.

Pneumonia of the wandering type may simulate this condition, but the character of the signs, with dullness and tubular breathing, and the rusty sputum, usually render diagnosis easy.

Prognosis.—This is very grave. The mortality is high, often as much as 50 per cent. Cases extending to 3 weeks or more with swinging temperatures usually recover.

Treatment.—Cases of this disease should be isolated. If there are indications of an epidemic spread, prophylactic inoculations with a vaccine made from the special strain of pneumococci concerned may be useful in limiting it. When once the disease has set in, unfortunately little except symptomatic treatment is available. The steam tent and the inhalation of medicated vapours, such as vapor benzoini, may give a little relief to the dyspnœa. Oxygen has not been found beneficial, though it may be tried. Venesection may give temporary relief, but produces no lasting effect. Ammonium carbonate and potassium iodide are generally recommended. Stimulants, such as brandy and strychnine, should be given freely, and hypodermic injections of camphor in sterile oil up to 10 or 20 grains a day may be given. Vaccines have so far not proved of any curative value.

SECONDARY BRONCHITIS

Ætiology.—Bronchitis, usually of catarrhal type—indistinguishable as regards symptoms and signs from primary acute catarrhal bronchitis—occurs as a definite part of many acute infectious diseases and as a complication in others. Among these may be mentioned measles, whooping-cough, influenza, the enteric group, small-pox, diphtheria, malaria and plague. Acute

nephritis of infective origin is often accompanied by acute bronchitis. Other conditions associated with bronchitis are pulmonary tuberculosis, glanders, secondary syphilis, pleurisy and gunshot wounds of the chest.

Diagnosis.—Bronchitis is easy to recognise, but it is important not to overlook the fact that it may not be the primary condition. In all cases of bronchitis in the early stages, the possibility of a primary acute specific infection should be borne in mind. The diagnosis is also of importance in regard to treatment—for example, in malaria, nephritis and syphilis, in which treatment directed to the primary condition may be more helpful than the ordinary treatment of catarrhal bronchitis.

BRONCHITIS DUE TO MECHANICAL AND CHEMICAL AGENCIES

Ætiology.—*Mechanical.*—Attacks of acute bronchitis may be caused by the inhalation of dust-laden air. In occupations where the worker is liable to inspire fine particles of carbon, silica, steel, iron or kaolin, acute bronchitis may result, but more often these conditions lead to chronic bronchitis and pneumokoniosis. Pressure on a bronchus by aneurysm or new-growth, or irritation by the presence of a foreign body, may induce local acute bronchitis. The symptoms and signs are practically identical with those of the catarrhal form and need no special description.

Chemical.—Acute bronchitis may follow the inhalation of chemical irritants, either as a result of occupation, accidents, attempts at suicide, or the use of poison gases in warfare. Special attention has been drawn to this subject by the large number of cases of “gassing” dealt with in the Great War. Death not infrequently occurred, much acute suffering was caused, and some permanent damage has resulted in many cases which recovered. “Mustard gas” produces its chief effects upon the skin, the eyes and the bronchi. A fibrinous exudate forms on the mucosa as a false membrane, which separates as a slough. The suffocative gases chlorine and phosgene affect the alveoli primarily and more intensely. Chlorine inhaled in a concentration of 1 in 10,000 causes a rapid alveolar flooding with a serous and highly albuminous fluid, and if the victim does not die at once he is liable to suffer from an acute bronchitis. A condition called bronchiolitis fibrosa obliterans has been described as a sequel. It is often associated with asthmatic dyspnoea.

Symptoms.—These are similar to those of acute catarrhal bronchitis, but there is great pain, distress and almost constant cough, often with copious expectoration.

The treatment is referred to under the heading of Tracheitis, and is, in the main, symptomatic and directed to the relief of pain, useless cough, and distress.

ACUTE FIBRINOUS BRONCHITIS

Synonym.—Acute Plastic Bronchitis.

Definition.—A comparatively rare acute disease in which there is inflammation of the bronchi, with the formation of casts. These may be hollow or solid, and are coughed up in the expectoration.

Ætiology.—The cause of the disease is unknown. It is more common in males, and is met with both in children and in adults. It may begin as a

primary catarrhal bronchitis, or develop as a complication of enteric fever, measles or pulmonary tuberculosis. Such organisms as the pneumococcus or a streptococcus may be found in the casts.

Pathology.—The casts may involve the main bronchi only, or more frequently the smaller ones and the bronchioles. They are greyish white, solid or tubular, and when large, bear the impress upon their exterior of the bronchial walls in which they have been enclosed. Thus, when a cast extends up to the lower portion of the trachea, the indentations made by the tracheal rings may be seen impressed upon it. The fine terminations generally show a spiral moulding. Chemically, they consist of fibrin or of fibrin and mucin. Post mortem, the casts may be seen in some places *in situ*; in other areas the bronchi from which they have been expelled may be recognised. The bronchial mucous membrane is at times acutely inflamed, red in colour, with the lining epithelial cells desquamating, or it may appear pale and unaffected. There is usually a certain degree of emphysema, and there may be collapse of lung tissue beyond the site of obstruction.

Symptoms.—The disease generally begins somewhat abruptly with a cough and malaise. In the course of a few days the patient becomes considerably worse, dyspnoea develops and a certain degree of pyrexia, but the temperature is often not more than 99° or 100° F. The dyspnoea becomes more intense, and is the prominent and all-important symptom. The face is seen to be cyanosed, the alæ nasi and the accessory respiratory muscles are in violent action, sometimes with retraction of the intercostal spaces. There may be diminished movement of the chest, either bilateral or unilateral. If there is unilateral pulmonary collapse the heart may be slightly displaced towards the same side. Vocal fremitus may be normal or locally diminished. The percussion note is somewhat hyper-resonant over the anterior chest-wall, but behind there may be some degree of dullness over one or other lobes. If the bronchi are unilaterally affected there may be dullness limited to one lower lobe, with diminution of air entry and no adventitious sounds. Vocal resonance over the affected area is lessened. There is usually some diffuse bronchitis, as indicated by the presence of rhonchi or râles. Marked stridor is sometimes heard with respiration. A special sign, the “bruit de drapeau,” has been described when the cast lies free in the bronchial lumen. It is a dry clicking sound, caused by the flapping of the cast against the wall of the bronchus as the air passes over it. The ordinary sputum does not show any peculiarities. It may, however, show Curschmann’s spirals, Charcot-Leyden crystals and eosinophile cells, and it may be absent until the crisis occurs. This consists in the expectoration of the cast after a violent fit of coughing. The cast may be stained with blood, or there is sometimes actual hæmoptysis. The peculiar nature of the expectoration often escapes notice, unless it is examined by floating in water, when a large intact cast is revealed. The dyspnoea ceases immediately after the cast has been expelled.

Complications and Sequelæ.—Emphysema may occur as the result of the violent coughing, or the disease may become chronic, recurring at intervals of varying duration. The most serious complication is laryngeal obstruction, caused by the cast becoming impacted between the vocal cords.

Course.—The disease is generally self-limited, terminating with the separation and expectoration of the cast. The acute stage does not, as a rule, continue for more than 12 to 24 hours.

Diagnosis.—The stridor and respiratory obstruction are suggestive of œdema of the glottis, but auscultation will show that the site of the lesion is lower down the respiratory tract. Asthma, and all causes of laryngeal and tracheal obstruction, must be excluded. The dyspnoea and the presence of signs localised to one lobe may suggest an active lobar collapse, or a lobar pneumonia, but the dyspnoea is more intense than is met with in either of these conditions. Casts are expectorated in diphtheria, pneumonia, chronic disease of the heart, pulmonary tuberculosis and hæmoptysis. The casts of acute fibrinous bronchitis are firmer than those found in these affections, and are expectorated in long pieces, showing the many branches and bifurcations of the bronchial tree.

Prognosis.—The immediate outlook is fair. Death may occur in the first attack, or recurrences may take place, which lead to an increasing degree of emphysema, with its usual results. The ultimate prognosis is, therefore, not good.

Treatment.—The patient should be kept in bed and treated as a case of acute bronchitis. Inhalations of medicated vapours often afford relief. Potassium iodide is believed to expedite the separation of the cast. Intra-tracheal injections of olive oil or lime water have been recommended, as the casts tend to dissolve in the latter. Tracheotomy instruments should always be at hand in case of laryngeal impaction.

CHRONIC BRONCHITIS

Chronic bronchitis is perhaps even more difficult to classify than the acute varieties, each one of which may have its counterpart in chronic form, so that the same classification may be followed. At the same time it must be admitted that, especially in the catarrhal forms, the clinical manifestations are somewhat varied.

CHRONIC CATARRHAL BRONCHITIS

Ætiology.—The causes are practically identical with those of the acute form, of which it is in most cases a sequel.

This affection may commence at any age, although it is more common in middle life and with advancing years. Men are more frequently affected than women. It seems also to have a special incidence in some families. It is more common in damp and foggy climates, and is favoured by urban conditions and by dusty occupations. It starts each winter with a more or less acute catarrhal attack, but each year the summer intermission becomes shorter, until the bronchitis persists throughout the year. It tends to produce emphysema and is aggravated in turn by this condition. It is especially favoured by cardio-vascular lesions, such as valvular defects and arterial disease; also by gout, chronic nephritis, syphilis and alcoholism. Conditions associated with chronic cough predispose to it, notably emphysema, asthma, arrested pulmonary tuberculosis, mouth-breathing and cigarette-smoke inhaling.

The bacteria found are practically identical with those in acute bronchitis, the commonest being the pneumococcus, Friedländer's pneumobacillus, *Micrococcus catarrhalis*, streptococci and staphylococci. Mixtures of two

or more of these may be present. A rarer cause is bronchial spirochætosis, from infection with the *S. bronchialis*.

Pathology.—The bronchi show chronic inflammatory changes of a catarrhal nature. The walls are thickened from chronic hyperæmia and also from productive changes in the connective tissues. The mucous glands may be hypertrophied or atrophied, and there may be widespread desquamation of the ciliated epithelial lining of the bronchi. In long-standing cases there is usually some peribronchitis, leading to cylindrical bronchiectasis and distortion of the bronchi by fibrosis. There is almost invariably a greater or less degree of emphysema, which may be generalised or only marginal. Post mortem, the lungs are generally red and somewhat engorged, but if much emphysema has resulted they may be paler than normal. On squeezing the lung after section, pus or muco-pus exudes from the cut bronchi, and there is usually some evidence of œdema at the bases.

Symptoms.—A patient with chronic bronchitis complains of his "chest." By this he means that he suffers from cough, expectoration and shortness of breath on exertion. The cough varies greatly in its severity. During the warm weather the patient may be completely free, and yet suffer for years from a winter cough. It may occur frequently throughout the day and in attacks at night, or only in the mornings and evenings.

The expectoration varies considerably in quality and quantity, so much so that the old classifications of chronic bronchitis were based on this factor. Thus, there may be practically no sputum or only small tenacious pellets, the "crachats perlés" of Laennec, which gave rise to the name "catarrhe sec"; on the other hand, there may be a profuse expectoration resembling unboiled white of egg diluted with water, constituting the form described as "pituitous catarrh" or "bronchorrhœa serosa." Usually the sputum is mucous or muco-purulent and contains greyish-black particles mixed with a frothy fluid. The dyspnœa is largely due to the accompanying emphysema, and so indicates the degree of chronicity of the disease. At first the patient may only notice that he gets out of breath on going upstairs or on mounting slopes, but later even walking on the level causes dyspnœa.

Slight rises of temperature occur in the acute exacerbations of the catarrhal process. Slight cyanosis is frequently observed, especially after exercise, when the accessory respiratory muscles are called into play. Sometimes rhonchal fremitus is felt. Movement of the chest is restricted by emphysema, and the percussion note then becomes hyper-resonant. On auscultation, expiration is prolonged and sonorous or sibilant rhonchi are heard all over the lungs, with bubbling râles if there is thin secretion in the smaller bronchi. On the other hand, rhonchi may be scanty or only occasionally heard. Voice conduction is unaffected. The fingers may be slightly clubbed, and further evidence of venous obstruction apparent in the dilated venules on the cheeks or along the costal attachments of the diaphragm.

Complications and Sequelæ.—The following changes may occur in the lungs—peribronchial fibrosis, bronchiectasis and emphysema. Asthma or attacks of bronchial spasm sometimes form a complicating factor in chronic bronchitis, especially in the cases of so-called bronchorrhœa. The increased cardiac strain may lead to right-sided dilatation, with basal pulmonary congestion, ascites and œdema of the legs. Late in the disease, as the result of the cyanosis, a peculiar form of confusional delirium is met with, which is

worse at night. Trophic lesions, such as dermatitis herpetiformis and pulmonary arthropathy, are occasionally seen.

Course.—The disease once firmly established, unless relieved by suitable climatic treatment, remains chronic and becomes progressively more severe as further damage is wrought in the lungs with each hibernal exacerbation. As the emphysema develops, a vicious circle is initiated, the aerating power of the lungs diminishes, and finally cardiac failure ensues.

Diagnosis.—Chronic bronchitis must be distinguished from pulmonary tuberculosis, bronchitis secondary to heart failure, and from bronchiectasis. In tuberculosis with bronchitis there is generally wasting, and often flattening of the chest-wall, owing to fibrosis of the lungs. In all cases where the summer intermission of the symptoms fails suddenly rather than lessens gradually, tuberculosis should be suspected. The diagnosis is clinched by the presence of tubercle bacilli in the sputum. In bronchitis secondary to heart failure, in addition to the cardiac signs, the râles in the lungs are chiefly basal and the rhonchi are not so universally distributed. In bronchiectasis the signs are usually characteristic and limited to one lobe. The X-Rays may afford useful aid in diagnosis.

Prognosis.—The immediate prognosis is good, the ultimate is bad. Much depends upon the patient's social condition and opportunities for treatment, especially in respect to climate. The expectation of life of a patient suffering from chronic bronchitis is considerably shortened.

Treatment.—Those subject to chronic bronchitis should live in a warm, equable and dry climate. In England the south-western districts are best, but it is advisable to winter farther afield if possible, either on the Riviera, the north coast of Africa, or in Madeira. High altitudes should be avoided if emphysema is present or if there are cardiac complications. Exposure to wet and chill is dangerous. The question of occupation is often difficult. Much time should be spent out of doors, provided that the patient is not exposed to the inclemencies of the elements; and, further, the work undertaken must not involve severe muscular efforts, or the inhalation of dusty or irritant particles.

In England it is difficult to find an outdoor occupation conforming with these desiderata, consequently light indoor work in a good atmosphere should be advised. Clothing should be warm but light, and afford special protection to the chest without overloading, as some patients are liable to do. Excesses in diet are to be avoided, also alcohol and heavy smoking. The general nutrition should be well maintained, and many patients, especially those of spare habit, seem to derive great benefit from cod-liver oil during the winter months.

If cough is troublesome and expectoration tenacious or scanty, various combinations of expectorant remedies are useful, such as ammonium carbonate or chloride, tinct. ipecacuanhæ, preparations of squills or senega, with tolu, liquorice or Virginian prune as flavouring agents. A simple saline mixture, such as the "Mist. sodæ cum æthere chlorico"¹ of the Brompton Hospital Pharmacopœia, in the morning or at night, may help to "clear the tubes" and give the patient a spell of freedom from cough. In older patients the ether and ammonia mixture may be given, and in cases with bronchial spasm potassium

¹ ℞. Sodii bicarb., grs. x; sodii chlorid., grs. iij; sp. chlorof., ℥v; aquam anisi ad ʒi.

iodide with anti-spasmodics, such as stramonium, lobelia, belladonna or grindelia, may be of great value. Various antiseptic drugs, such as turpentine M x, terebene M v-x, creosote M iij in capsules or perles, have been recommended, and the elixir thymi et diamorphin. 5i. Sedative lozenges, such as the compound liquorice, heroin or codeine, are often useful in checking useless cough. Intercurrent attacks of acute bronchitis must be treated on the principles described under that condition and the patient kept indoors or in bed, as may be necessary. When an advanced degree of emphysema coexists the treatment appropriate to that condition should be applied. Sometimes benefit may follow the use of the compressed air chamber. When failure of the right heart ensues, with visceral engorgement, the treatment must be modified suitably as described under emphysema. Liniments applied to the chest-wall, especially those containing camphor, turpentine or belladonna, are soothing and afford relief. Care should be taken that any tendency to constipation is checked. In some cases, especially when the predominant organism is the *Micrococcus catarrhalis* or Friedländer's pneumo-bacillus, an autogenous vaccine prepared from the sputum ameliorates the symptoms. This should be considered especially in cases unable to undergo suitable climatic treatment.

CHRONIC SUPPURATIVE BRONCHITIS

Synonym.—Fœtid Bronchitis.

Ætiology.—This condition is not sharply defined and is not a specific and separate nosological entity, but it is a convenient group to include cases with fœtid purulent sputum. In some forms of chronic bronchitis the secretion may from time to time accumulate in the bronchi and prove offensive on expectoration. In some instances this condition becomes chronic and the expectoration is fœtid up to the time of death.

Pathology.—There is chronic inflammation of the bronchi, with marked peribronchial thickening. The bronchial secretion becomes purulent, and ulceration of the bronchial wall or dilatation of the lumen may occur. Post mortem, the lungs are soft, and on section some broncho-pneumonic areas, with œdema of the bases, may be seen. Pus of an offensive nature exudes from the cut ends of the bronchi.

Symptoms.—These resemble those found in chronic bronchitis, with, in addition, the unpleasant characteristics of the sputum. In the latter, Dittrich's plugs may be found. These are small, yellowish bodies, with an intensely offensive odour, composed of compact secretion.

Complications and Sequelæ.—Ulceration of the bronchial walls, abscess or gangrene of the lung, and areas of broncho-pneumonia may develop. As with bronchiectasis, pyæmia sometimes ensues, with the formation of secondary abscesses in the brain.

Course.—The disease is progressive, but in the early stages there may be long remissions in which the sputum is not offensive although the bronchitis persists.

Diagnosis.—The sputum is offensive in abscess and gangrene of the lung, bronchiectasis and interlobar empyema. X-Ray examination of the chest is of great value in revealing these conditions, and lipiodol investigation will usually serve to distinguish between them.

Prognosis.—As the disease becomes firmly established the patient's strength is gradually undermined from the absorption of toxins, and death ensues in the course of a few years, either from exhaustion, toxæmia or pyæmia.

Treatment.—An endeavour should be made to lessen or prevent the offensive character of the sputum. For this purpose creosote or garlic may be administered, as in bronchiectasis. Creosote vapour baths are also of great value. Apart from this, the treatment is as for chronic bronchitis.

CHRONIC SECONDARY BRONCHITIS

Chronic bronchitis is a common association of chronic cardiac and renal disease, and possibly also of gout. Its clinical characters do not need special description. It is only necessary to emphasise, as in the acute forms, the importance of recognising that the bronchitis is not the essential condition, and that treatment must be directed especially to the primary disease.

CHRONIC BRONCHITIS FROM MECHANICAL AND CHEMICAL AGENCIES

This usually proceeds to interstitial changes in the lung, and these results may be studied more conveniently under the heading of the pneumokonioses.

CHRONIC FIBRINOUS BRONCHITIS

Acute fibrinous bronchitis has been described above. In certain cases of chronic catarrhal bronchitis a fibrinous exudate may occur from time to time, with the formation of intrabronchial casts. There is then cough and dyspnœa, which abate with the expectoration of the cast. It therefore very closely resembles acute fibrinous bronchitis, and the treatment indicated is that described above.

TUMOURS OF THE BRONCHI

Tumours arising in the bronchi are somewhat uncommon. They may be (a) simple, or (b) malignant.

Simple tumours.—The following varieties occur: Adenoma, lipoma, myxoma, papilloma and chondroma. Any of these may lead to bronchial obstruction and, in consequence, to either collapse or bronchiectasis, but otherwise they rarely give rise to symptoms or physical signs, and they are for the most part only of pathological interest.

Malignant tumours.—Primary carcinoma or sarcoma may originate in the bronchi. In carcinoma the growth is usually of the columnar type, and arises from the lining epithelium of the bronchi or from that in the mucous glands. Oat-celled tumours also occur, and occasionally squamous-celled carcinoma. In some instances secondary deposits of carcinoma may follow very closely the paths of the main bronchi. Sarcoma may originate in the connective tissue of the bronchial walls.

Diagnosis from carcinoma of the lung (see p. 1195) and from mediastinal sarcoma (see p. 1250) may be very difficult, since the symptoms and signs may be almost identical. Lipiodol and bronchoscopic investigations may, however, enable a correct diagnosis to be made.

THE INFECTIVE GRANULOMATA

SYPHILIS.—During the secondary stage, a generalised hyperæmia of the bronchial mucous membrane may occur, giving rise to slight bronchial catarrh with the usual symptoms and signs, a condition that has been called syphilitic bronchitis. It is frequently beneficially influenced by anti-syphilitic treatment. In the tertiary stage, gummata may form in or near the large bronchi. They tend rather to fibrosis and contraction than to softening and ulceration, although the latter processes may occur. Contraction may lead to bronchial stenosis, with the symptoms and signs described below, or to extensive peribronchial inflammation and bronchiectasis. If the gummata extend into the lung, as may happen in rare instances, destructive lesions with cough, expectoration and hæmorrhage may result. This condition is more fully described in the section on pulmonary syphilis.

TUBERCULOSIS of the bronchi occurs as part of pulmonary tuberculosis and does not require separate description.

LEPROSY.—The bronchi may be involved in this disease, with the production of cellular infiltration and even nodule formation. At first, these lesions may produce bronchitis, but they are progressive and lead to cough, expectoration, wasting and asthenia. The general clinical picture may simulate chronic pulmonary tuberculosis, from which it is distinguished by the presence of leprous lesions elsewhere, and the absence of tubercle bacilli from the sputum.

BRONCHIAL STENOSIS AND OBSTRUCTION

Obstruction of the main bronchi or of their subdivisions within the lungs may arise from causes within the bronchi or from conditions outside them, and these require separate consideration. It is important to emphasise the fact that in both conditions the symptoms differ according to whether the obstruction is sudden and complete, in which case collapse of the corresponding lung is the rule, or whether it is partial and more gradual, when bronchiectasis usually results.

Obstruction of the smaller bronchi may result from spasm as in asthma (see p. 1125) or from disease as in small-tube and capillary bronchitis (see p. 1110).

1. INTERNAL CAUSES

These are most conveniently considered in two groups—(a) Foreign bodies; (b) those due to disease or cicatrisation of the bronchial walls.

(a) **FOREIGN BODIES IN THE BRONCHI.**—These usually gain access through the larynx and trachea by inhalation. Any inhaled foreign body that is small enough to pass down the trachea may reach a main bronchus, more commonly the right, or if it is small it may pass into one of the secondary bronchi. It may at once become impacted, or be moved by cough, but unless it is expelled in this way, it is sooner or later drawn into the smallest bronchus that will receive it, and there becomes impacted.

The recorded varieties of foreign body thus reaching the bronchi are

very numerous, but among the more common are pieces of bone, beads, pins, coins, ear-rings, studs, pencils, fruit stones, grains, grasses, beans, nuts, teeth and pieces of tonsil or adenoid growths after tonsillectomy. Even a living fish has been inhaled into a bronchus. Foreign bodies may reach the bronchi through a tracheotomy wound, or a gland may ulcerate into the lumen of a bronchus. Broncholiths and pneumoliths, calcareous particles originating in the bronchi and lungs respectively, may be inhaled into a bronchus instead of being expectorated.

Pathology.—The pathological changes resulting from a foreign body in a bronchus depend upon the nature of the foreign body, the duration of its stay, the size of the bronchus obstructed by it, and the degree of obstruction induced. If the foreign body is smooth and comparatively little septic, and if it be removed within 24 hours or so, complete recovery after a very mild local inflammatory reaction may be expected. If, on the other hand, the foreign body is rough, or soft and laden with septic organisms, acute pneumonic processes, often septic in character, may develop very rapidly. A soft type of foreign body may swell and completely obstruct the bronchus it reaches, leading to complete collapse of the corresponding lung area, often the whole or half of the lower lobe. If the stay of any foreign body is prolonged to days, weeks, months or longer, irreparable damage almost invariably results. The forms this may take are numerous. Collapse and septic pneumonia have already been mentioned. If the obstruction is partial, septic bronchitis, with stagnation of the bronchial exudate and pus behind the obstruction, leads in turn to peribronchitis, bronchiectasis and fibroid induration of the corresponding lung area. In other cases gangrene of the lung results. Not infrequently an empyema may occur and the foreign body may be found in the empyema cavity. Suppuration round a foreign body may lead to localised intrapulmonary suppuration or abscess.

Symptoms.—During the passage of the foreign body through the larynx and trachea urgent symptoms may occur which leave no doubt as to what has happened; but this is not invariable, and the patient may not be sure whether he has inhaled or swallowed it. In any case, after a bronchus has been reached, there may be a latent period which engenders a sense of false security and leads to delay in treatment. In most cases pain, discomfort and cough develop rapidly. The cough may lead to the expulsion of the foreign body, or may cause dyspnoea if it forces it up to the larynx. The cough soon becomes noisy, often paroxysmal, and if local septic changes are set up expectoration occurs, sometimes mucoid and copious, at others muco-purulent. Pain may be absent, but is often severe. The temperature is generally normal for the first few hours, but soon rises, especially if bronchitis, pneumonia or broncho-pneumonia develops. The further symptoms are those of the reactive changes and complications which ensue.

The physical signs naturally depend upon the bronchus affected and upon the degree of obstruction. They are at first those of deficient air entry. The affected side may show less movement, and there may be some recession of the lower intercostal spaces in young people. If a large bronchus is involved and collapse results, there is some displacement of the heart to the affected side. Vocal fremitus may be diminished or absent, the percussion note impaired, and the breath-sounds and voice-sounds weak or absent over

the whole or part of one lung, almost invariably the lower lobe. An "asthma-toid wheeze" has been described in America. This consists of a wheezing sound heard at the end of inspiration on listening close to the open mouth when the patient breathes deeply. When bronchiectasis, empyema or other conditions develop, their characteristic signs become apparent.

Complications and Sequelæ.—Many of these have been enumerated in describing the pathological results. Sometimes septic meningitis or cerebral abscess develops.

Course.—Spontaneous relief may occur in two ways, either by the foreign body being coughed up, as may happen within a few hours or days or after an interval of months or years, or the foreign body may track through the lungs and pleura, and be discharged in an abscess bursting through the chest wall. In both cases, if an interval of more than days occurs, irrecoverable damage may have resulted. Apart from these occurrences and from successful treatment the course is very variable. Death may occur quickly from some of the septic complications, or after a longer or shorter interval from bronchiectasis, gangrene or cerebral abscess.

Diagnosis.—The history of disappearance of some article from the mouth in the act of laughing, breathing, yawning or sighing, etc., should always arouse suspicion of an inhaled foreign body. If signs indicating bronchial obstruction are found, the diagnosis is almost certain. In every suspicious case radiograms of the chest should be taken in two different directions, in case the shadow may be merged in that of the scapula or of the ribs. The possibility of a foreign body should always be borne in mind in cases of unilateral basic bronchiectasis, especially if no obvious cause can be found. When such unilateral lung signs develop after an anæsthetic, or after operations on the mouth or naso-pharynx, the possibility of some inhaled material should always be remembered.

Prognosis.—This is grave unless the foreign body is removed within 36 hours, owing to the various dangerous complications that may ensue. Excluding the few cases in which cure occurs by spontaneous discharge of the foreign body, about 50 per cent. of cases left untreated die within 1 or 2 years.

Treatment.—This consists in removal, if practicable, as soon as possible after the diagnosis is established. If the foreign body is in a main bronchus or one of its principal divisions it can usually be removed by means of the bronchoscope and appropriate forceps. The operation requires very careful anæsthesia and expert manipulation. Where these are not available a tracheotomy may be done, when sometimes the foreign body is coughed out or can be extracted. If these methods fail the question of pneumotomy may have to be considered. If this is decided on, every effort must be made to localise the foreign body by X-Ray examination. If intrapulmonary or pleural suppuration has occurred, this must be dealt with surgically, and sometimes the foreign body can be removed at the same time. The medical treatment of the cases consists in that of the various conditions resulting.

(b) **STENOSIS FROM DISEASE OR CICATRISATION OF THE BRONCHIAL WALL.**—**Ætiology.**—Primary bronchial new-growths, including columnar-celled carcinoma, oat-celled tumour and squamous-celled carcinoma lead to bronchial obstruction at an early stage. These conditions produce symptoms and signs practically identical with those of new-growths in the lung (see p. 1194).

The causes of cicatrisation are those leading to ulceration of the bronchial wall, with subsequent healing, such as syphilitic processes in and around the bronchi, ulceration from injury produced by a foreign body or in its removal, or by the inhalation of severe irritants. The fibroid variety of tuberculosis may also produce it.

Pathology.—The stenosis may occur in one of the main bronchi, or in one passing to a lobe or to part of a lobe. At first partial, it may progress, until the lumen is almost completely occluded at one point. The changes occurring in the lung beyond the obstruction vary with its degree. At first there is retention of secretion in the bronchi, and air may be forced past the obstruction in inspiration, but not expelled during expiration, producing emphysema, with commencing bronchial dilatation. When the obstruction is more complete the air is absorbed, the lung tissue gradually becomes fibrotic, and the bronchi dilate further.

Symptoms.—Cough, not infrequently of paroxysmal character, is an early symptom and is usually a continuation of that caused by the primary condition. It may be dry or associated with mucoid sputum, sometimes blood-streaked. The expectoration may cause dyspnoea, by obstructing the narrowed bronchus. If bronchiectasis develops the sputum becomes foetid.

The physical signs are those of collapse of a part of the lung and are progressive. Local limitation of movement and flattening, with displacement of the heart to the affected side, may be apparent on inspection. The vocal fremitus is diminished, the percussion note, impaired at first, may progress to complete dullness when fibrosis develops. The breath-sounds are weak or even absent, and the voice-sounds diminished. In the early stages a bronchial stridor may be audible. Compensatory emphysema of the adjacent healthy lung tissue often develops.

Complications.—These are similar to those in stenosis from a foreign body, notably fibrosis and bronchiectasis.

Course.—Unless the primary condition causing the stenosis is one which can be arrested by treatment, the condition is progressive, and eventually the area of lung beyond the obstruction becomes permanently functionless.

Diagnosis.—Bronchial cicatrisation must be differentiated from obstruction due to extrabronchial causes, such as pressure from new-growths, aneurysm and the other mediastinal conditions mentioned in the section below. The history, the physical signs and examination by X-Rays and possibly by the bronchoscope may help in distinguishing. The Wassermann reaction should be investigated in every case where the stenosis is proved to be of intrabronchial origin.

Prognosis.—This varies with the cause. It is most favourable in cases due to syphilis submitted to treatment at an early stage.

Treatment.—Vigorous anti-syphilitic treatment should be employed in cases due to syphilis. In other cases the treatment is to relieve symptoms by appropriate measures.

2. EXTERNAL CAUSES

These may be subdivided into—(a) *Mediastinal conditions*, chiefly enlargement of the bronchial or mediastinal glands from tuberculosis, Hodgkin's disease or malignant growth, aneurysm of the aorta, mediastinal abscess.

pericardial effusion and œsophageal new-growths. (b) *Intrapulmonary causes*, generally primary or secondary new-growths.

Symptoms.—These are practically identical with those just described, but in addition there are those of the condition causing the pressure.

Diagnosis.—This has been discussed in the previous section. The bronchoscope should not be employed where there is any suspicion of an aneurysm.

Prognosis.—This is extremely unfavourable, except in cases due to tuberculous glands and pericardial effusion, and in some cases of mediastinal suppuration.

Treatment.—This can only be palliative in the majority of cases. Useless cough may be checked by a sedative linctus of heroin or morphine. Dyspnoea when due to spasm may be lessened by inhalations of creosote and spirits of chloroform, or by administration of oxygen. Pain may be relieved by aspirin or other analgesic drugs.

ASTHMA

The term asthma has been loosely employed to denote any form of dyspnoea of expiratory type occurring in paroxysms. For all conditions other than that now to be described some descriptive qualification should be employed to avoid confusion.

Asthma or true spasmodic asthma is a paroxysmal affection, occurring most frequently in patients of neuropathic inheritance. It manifests itself in attacks of severe expiratory dyspnoea due to excessive vagal discharges, set free by peripheral irritation, chemical agencies or cerebral influences.

Ætiology.—Probably no other disease shows such a varied and complex causation, but studies of idiosyncrasy and anaphylaxis have served to explain many of the obscurities.

Predisposing causes.—*Age.*—The first attack may occur at any age, even as early as the period of the first dentition. The majority of cases begin before the age of 25.

Sex.—Asthma is generally stated to be nearly twice as frequent in the male sex as in the female.

Heredity.—Asthma certainly runs in families. The heredity is not always direct, the nervous instability sometimes being evidenced in other generations by migraine, epilepsy or hysteria. The view that hypersensitiveness to certain proteins is inherited is now discredited, and it is believed that an unduly irritable bronchial centre is the factor transmitted by heredity.

Other diseases.—Gout and syphilis are said to predispose to asthma. Bronchitis not infrequently leads to paroxysms in patients with asthmatic tendencies. Tuberculosis of the lung occasionally induces it, but here again it is probably in patients with the asthmatic diathesis.

Climate and locality.—Asthmatics seem very sensitive to both of these, but no general relationship can be proved, as the effects are most variable. Some patients are better in dry, others in damp, foggy climates, and in regard to locality each patient is a law to himself.

Conditions of the nose and naso-pharynx.—Nasal obstruction from swelling of the turbinates, deflection of the septum, spurs and polypi, and conditions

of the naso-pharynx, such as adenoids and enlarged tonsils, undoubtedly predispose to asthma, and may also be exciting causes of the actual paroxysm.

Exciting causes.—Chemical substances.—The emanations from certain animals may be the determining cause. The best known of these are the horse and cat, but rabbits, hares, guinea-pigs, deer, dogs and monkeys may have a similar effect. Even human hair appears capable of discharging the paroxysm. The dust from some substances, such as corn, rice or oats, the smell of certain drugs, such as ipecacuanha, and the scent and the pollen of grasses and flowers may act in a similar fashion, as also may articles of diet, and many drugs. This factor in causation has attracted much attention—in this country by Freeman and Coke, and in America by Walker. It is claimed that at least 50 per cent. of asthmatics show hypersensitiveness to various protein antigens obtainable from animals, grains, bacterial bodies, foods and drugs, and over a hundred are now available for routine testing of these patients. The analogy with the causation of hay fever and paroxysmal sneezing is obvious.

Peripheral irritation.—As already mentioned, irritation of the nose, naso-pharynx and bronchi may be asthmogenic in those of asthmatic tendency.

Gastro-intestinal disturbance.—This is well recognised as a cause, and most asthmatics find by experience the penalties of a heavy late meal and of indigestible articles of diet. It is possible that actual metabolic errors may be a factor, as in the so-called "week-end asthma," due to altered conditions of diet and exercise at this period.

Genito-urinary conditions, particularly in women, notably ovarian or uterine disorders, sometimes act in inducing asthma.

Cutaneous.—Asthmatics are peculiarly liable to urticaria and eczema, although these conditions usually alternate with the asthmatic attacks.

Nervous factors.—Fatigue, emotion and nervous shock may precipitate an attack. This factor cannot be ignored, even in cases due to protein hypersensitiveness, as is shown by a well-known case in which a patient susceptible to roses developed asthma when handed an artificial rose.

Pathology.—Numerous theories have been propounded to explain the asthmatic paroxysm. Among these may be mentioned vascular turgescence of the bronchial mucous membrane, spasm of the bronchial muscle, and increased secretion of the mucous glands. Spasm of the diaphragm or of the inspiratory muscles has also been suggested. That bronchial spasm plays the major part seems to have been established by the experiments of Brodie and Dixon, and this view is strongly supported by their observations on the effects of drugs on the bronchial musculature. Muscarine, pilocarpine and physostigmine produce bronchial constriction and asthmatic symptoms in animals, while atropine, hyoscyanine and chloroform abolish these effects.

There can now be little doubt that the broncho-constrictor fibres of the vagus are the channel by which the impulses discharging the asthmatic paroxysm reach the bronchi, although the possibility that impulses leading to vaso-dilatation and to increased bronchial secretion are also concerned, must be admitted.

ANAPHYLAXIS.—The important part played by extraneous proteins in the genesis of asthma and the obvious analogy between the asthmatic paroxysm and the symptoms of anaphylactic shock have suggested that in many cases, if not in all, asthma is an anaphylactic phenomenon. Evidence is accumu-

lating in support of this view. It has been shown that the lungs of the guinea-pig killed in anaphylactic shock show extreme constriction of the bronchioles. Asthmatics are well known to show anaphylactic tendencies, and especial care in the administration of antitoxic serums is necessary with them. It is of some interest to note that Eppinger and Hess' group of vagotonics show urticaria, dermatographia, eosinophilia and liability to anaphylactic shock, all conditions which occur in asthmatics. It is tempting, therefore, to assume that the foreign protein or toxin produces the asthmatic attack by inducing vagotonicity. Lastly, the observations of Freeman, Coke and the American workers have demonstrated the cutaneous hypersensitiveness of many asthmatics to special foreign proteins. Further research is needed before it can be accepted that anaphylaxis accounts for all cases of asthma, but it is almost certainly an important factor in many.

Asthma is rarely fatal apart from complications, so little can be stated about its morbid anatomy.

Symptoms.—The asthmatic paroxysm most commonly commences about 2 a.m. or later, but it may sometimes develop in the daytime. There are often preliminary indications some hours beforehand, constituting the "asthmatic aura." These include restlessness, irritability, mental exaltation, less frequently depression, itching of the nose or chin, flatulence or polyuria. Some attacks are ushered in by coryza. Such warnings are not constant, and the sufferer usually wakes from sleep with a feeling of suffocation. In early attacks great restlessness, anxiety and alarm occur. The difficulty in breathing and the sense of suffocation increase; the patient sits up in bed, or gets up to throw open the window, and fixes his arms to bring into action all possible muscles of respiration. Respiration, although laboured and difficult, is often slow, inspiration being short while expiration is greatly prolonged. Both are accompanied by loud wheezing sounds, audible at a distance from the chest. The patient appears pale, but the lips are dusky and the expression is anxious and distressed. The jugular veins are distended and prominent. The accessory muscles of respiration are seen to be in violent action, notably the sterno-mastoids, scalenes and pectorals. The skin is moist and there may be marked sweating. The chest is much distended, and at each violent attempt at inspiration very little further enlargement occurs, while there is often sucking-in of the supra-clavicular and lower costal regions.

Percussion reveals marked hyper-resonance and encroachment on the cardiac and hepatic dullness. On auscultation inspiration is short and high-pitched, expiration very prolonged, and both are obscured by abundant sonorous and sibilant rhonchi, and later by bubbling râles at the bases. The pulse is small, quick and sometimes irregular. There is usually marked epigastric pulsation. A differential blood count during an attack may show an eosinophilia of as much as 35 per cent. Cough does not develop until late in the paroxysm, and is quickly followed in many cases by the expectoration of small pellets, called "perles" by Laennec, and often likened to boiled sago or tapioca. These were carefully studied by Curschmann, and when examined on glass on a black background, prove to consist of a central highly refractive mucinoid coil, with masses and threads of mucin wrapped spirally around it. Microscopically leucocytes, mostly eosinophils, may be seen entangled in the mucus. The sputum frequently contains Charcot-Leyden

crystals, which are not now regarded as spermin phosphate but more probably as tyrosin. With the onset of expectoration the dyspnœa quickly lessens, and the attack subsides. The patient often passes a large quantity of pale urine and then may sleep until morning, awaking in apparent comfort. More frequently he appears pale, tired and anxious.

Course, Complications and Sequelæ.—Such an attack may last from a few minutes to several hours, and may remit and then return. When the spasm is very severe and prolonged into hours, with little or no remission, the condition is often termed "status asthmaticus." The patient may be extremely ill, and death may occur unless the attack remits spontaneously or as a result of treatment. More often the attacks recur at the same time each night for a considerable period extending to weeks, and then pass off, after which the patient may enjoy a period of freedom of weeks or months. The intermissions may become shorter with successive attacks, and increasing emphysema may develop. This in turn leads to secondary bronchitis, which persists, together with some degree of permanent œdema of the bases. Later still the cardio-vascular changes incidental to emphysema occur as sequelæ, namely, engorgement of the right heart, tricuspid regurgitation, venous stasis, ascites and œdema. Chronic asthmatics frequently present a characteristic appearance. Of thin build, with sallow complexion, anxious expression and nervous manner, they often have a long neck, high straight shoulders, and a forward stoop. Asthma necessarily imposes limitations upon those who suffer from it at all severely, although many asthmatics lead active, useful lives in spite of their disease.

Diagnosis.—This involves the differentiation from other forms of dyspnœa, particularly those of spasmodic expiratory type. The chief forms of paroxysmal expiratory dyspnœa are:

1. *Bronchial asthma or spasmodic dyspnœa complicating chronic bronchitis and emphysema.*—This condition is sometimes a late result of true asthma, but may occur independently. The dyspnœa is more persistent and is more definitely related to the bronchitic attacks, being therefore more common in the winter.

2. *Cardiac dyspnœa or cardiac asthma.*—This, like true asthma, is often nocturnal, but the signs of failure of compensation in association with valvular or myocardial disease usually make the nature of the dyspnœa clear.

3. *Uremic dyspnœa or renal asthma.*—This is also not infrequently nocturnal and may be almost indistinguishable from true asthma. Examination of the urine and the presence of cardio-vascular changes with high blood-pressure enable the distinction to be made with certainty, although the latter is not invariable.

4. *Hay asthma* is probably only a severe form of hay fever and is to be regarded as a variety of true asthma.

5. *Pulmonary tuberculosis may be associated with asthmatic dyspnœa.*—The differentiation may not be easy during the attack, but the persistence of apical signs in the interval may give a clue. It is a wise precaution to examine the sputum for tubercle bacilli in all cases of asthma. A low blood-pressure in an asthmatic should also arouse suspicion of tuberculosis.

The dyspnœa of laryngeal or tracheal obstruction and of mediastinal pressure can usually be recognised by the fact that it is chiefly of inspiratory type, and may be associated with stridor, instead of wheezing. In all cases

of doubt the chest should be examined with the X-Rays to exclude aneurysm or new-growth.

Prognosis.—When the disease starts in childhood or in early adult life it may stop spontaneously or be relieved permanently when some causal condition is discovered and treated. During a severe attack the aspect of the patient may be so alarming that a fatal issue may seem imminent, yet death very rarely occurs. In chronic cases, the ultimate prognosis is made more serious by the complicating emphysema and bronchitis, and in spite of popular belief, the asthmatic has less than the normal expectation of life.

Treatment.—(a) *During the attack.*—The list of anti-spasmodic drugs and measures employed is a long one, and it is impossible to foretell which will be efficacious, for asthmatics vary as widely in their response to drugs as they do in regard to asthmogenic causes. Drugs may be administered for this purpose by inhalation, by nasal sprays, by the mouth or by hypodermic injection. Adrenaline hydrochloride, in doses of 2 to 5 minims of a 1 in 1000 solution hypodermically, may act with dramatic efficacy if administered sufficiently early, but it should be given cautiously to elderly asthmatics. It may also be combined with pituitary extract, as in the special preparations evatmine, pitrenalin and asthmolysin. In status asthmaticus, the procedure suggested by Dr. A. F. Hurst may give relief. A syringe of 1 c.c. capacity is filled with adrenaline solution 1 in 1000. This is slowly injected over a period of several minutes to half an hour, or until the spasm relaxes. Ephedrine hydrochloride, in tablets of gr. $\frac{1}{4}$ to $\frac{3}{4}$, has proved itself a useful substitute for adrenaline in some cases and can be given by the mouth. Ephetonin, a synthetic preparation of similar character, is also sometimes employed. Adrenaline sometimes proves helpful as a nasal spray, especially in combination with chlorotone. A weak solution of cocaine and atropine in an oily excipient has been much employed as a nasal spray, but it is not devoid of risk if used indiscriminately. The fumes of burning nitre paper, or of a powder composed of tobacco, stramonium and nitre, sometimes help to relieve the distress, but they should be avoided in cases with bronchitic complications. Smoking a cigarette or a cigar may be helpful in patients who do not smoke habitually; others are helped by cigarettes containing stramonium. Inhalations of amylnitrite, ethyl iodide or chloroform may be tried in some cases. Various drugs have been employed, of which potassium iodide and bicarbonate with tincture of stramonium, hyoscyamus, lobelia or belladonna are the most useful. Twenty or 30 minims of liquid extract of grindelia every 20 minutes for three doses have been found useful in some cases. Other drugs which have been recommended are chloral hydrate, phenacetin and the other coal tar antipyretic drugs, euphine (caffeine tri-iodide) in drachm doses, and an emulsion of benzyl benzoate, 2 drachms over 2 hours. Other measures include drinking a cup of strong coffee, the application of a mustard leaf over the sternum, and placing the feet in hot water and mustard. In very severe cases, if all else fails, it may be necessary to inject morphine or heroin, but this should only be done after careful consideration, owing to the danger of inducing the morphine habit.

(b) *Between the attacks.*—The greatest care should be taken to discover and deal with any predisposing or exciting causes. The patient should live in that locality which his experience shows to be most suitable for him, and at present no rules can be formulated in advising on this matter.

* Diet requires careful consideration. Any article of diet to which the

asthmatic is susceptible should be entirely eliminated, and only the lightest of meals should be taken after midday. Glucose has proved to be helpful in some cases of asthma in childhood. It is recommended to give 3 drachms in lemonade or orange juice 3 times a day, with extra sugar and sweets at meals. Alkalis may also be given at the same time. Fatigue, over-work and emotional stress are to be avoided. Care should be taken to see that the bowels act efficiently. The general health should be maintained by every possible means. Arsenic may be given by the mouth, or subcutaneously as sodium cacodylate (gr. $\frac{3}{4}$ in \mathbb{M} xv water). During the period when the patient is having a series of attacks, iodide of potassium with one or more of the anti-spasmodic group of drugs such as stramonium, lobelia, belladonna and grindelia, may be given regularly with great benefit. Any local source of irritation in the nose or naso-pharynx should be dealt with adequately. Sometimes touching the nasal septum with the galvano-cautery may alone be efficacious. In cases complicated by bronchitis, the sputum should be examined bacteriologically, and a vaccine may be made from the predominating organisms. If these prove to be *Micrococcus catarrhalis*, or Friedländer's pneumo-bacillus, great benefit may result, but the patient should be told that the vaccine can only help the asthma by lessening the accompanying catarrh. Some cases associated with marked emphysema obtain considerable relief from compressed air baths, at first on alternate days, then daily, the course extending to 1 or 2 months.

Careful investigation of the question of protein hypersensitiveness should be undertaken, and the method of testing by means of the cutaneous application of various antigens is worth consideration. For this purpose, the particular protein antigen, or a series of such antigens, may be applied to the skin of the forearm in the form of powder, solution or paste, and superficial scarification is then effected by means of a sterile needle or scalpel. A positive reaction is shown by the development of an urticarial wheal surrounded by a hyperæmic area. A control scarification with normal saline or a paste free from protein should be made at the same time. A positive result may be expected in about 50 per cent. of asthmatic patients. If such a condition is established to one or more such substances, they should be avoided if possible; if not, the methods of desensitisation may be tried, but the results are frequently disappointing. The specific antigen may be employed in very minute doses by injection, starting, for example, with 1 minum of a $\frac{1}{100,000}$ solution and gradually increasing. Auld has endeavoured to achieve the same effect by intravenous injections of peptone. In adults $\frac{1}{10}$ gr. of Armour's No. 2 peptone is given for the first dose, successive doses being given every fifth day, increasing by $\frac{1}{80}$ gr. each time for 6 injections, when the dose is kept stationary for another three or four injections. In cases which fail to respond to such injection, he has suggested the use of "new serum peptone" injections, which consist of a mixture of the patient's own serum with agar solution and Armour's No. 2 peptone. These injections should not be given during an asthmatic attack.

A variety of "shock" treatment which has given good results is the intramuscular injection of sulphur oil (*huile soufrée*), 0.03 gramme in 1 c.c. This is given in doses up to 1 c.c. once or twice weekly over a period of weeks or months.

A gold salt, allochrysin, has recently been given intramuscularly in doses

of 0·05 gramme, followed in a week by 0·1 gramme, and then, if tolerated, up to 0·2 gramme at weekly intervals till a total amount of 2 grammes has been given.

Storm van Leeuwen has emphasised the importance of dust and of some moulds, notably the genus *Aspergillus*, in the genesis of asthma. He tries the effect of putting the patients in rooms supplied with air relatively dust free.

BRONCHIECTASIS

Definition.—Bronchiectasis is a condition of permanent dilation of one or more bronchi. When it occurs in the finer divisions it is sometimes described as bronchiolectasis.

Ætiology.—Bronchiectasis is invariably secondary, and may result from disease of the bronchi, the lung parenchyma or the pleura. Even the rare congenital cases are probably consequent on malformation, atelectasis or intra-uterine disease.

1. The bronchial conditions which may progress to dilatation are bronchitis, and any affection leading to partial bronchial obstruction, such as inhaled foreign body, stenosis from cicatrisation and external pressure from new growth or aneurysm. In children, measles and whooping-cough are not uncommon causes, especially when they follow one another in rapid succession, although either alone, if severe, may lead to it.

2. Conditions of the lung parenchyma which may cause bronchiectasis are unresolved pneumonia, broncho-pneumonia, collapse, syphilis and tuberculosis. Syphilis is rare and usually acts by leading to bronchial obstruction or stenosis. Fibroid tuberculosis is a common cause, but the clinical manifestations are as a rule marked by the primary condition. The pulmonary complications of influenza are not infrequently followed by bronchiectasis.

3. The pleural conditions which are followed by bronchiectasis are those which lead to pleural adhesion and are associated with pulmonary fibrosis notably chronic pleural adhesion, or empyema leading to prolonged or permanent collapse of the lung.

In a lesion with such diverse antecedents the age relations are necessarily indefinite. It may occur at any age, but is commonest in the third and fourth decades. It frequently commences in childhood, although the characteristic clinical manifestations may not develop until adult life.

Sex.—In most recorded statistics there is a striking preponderance in the male.

Social state.—It is noteworthy that bronchiectasis in its fully developed form is much more common in the poor than in the well-to-do.

Pathology.—Three factors in the pathogenesis of bronchial dilation have to be considered. (1) Weakening of the bronchial walls. This is admittedly the most important. Most of the conditions preceding bronchiectasis tend to induce severe bronchitis and peribronchitis, and thus render the walls more yielding. Where stagnation of secretion occurs, putrefactive and other organisms develop, producing tryptic ferments which may act injuriously upon the lining membrane. (2) Increased pressure on the walls thus weakened is the determining factor. This is generally expiratory in origin and due to the strain of cough. The actual pressure of secretion

accumulating behind an obstruction may promote yielding of the bronchial walls. In cases of bronchiectasis following on collapse of the lung the force of inspiration has been regarded as contributory, but this is doubtful and in any case is less important than the expiratory strain of cough. (3) The third possibility is the traction exerted upon the walls of the bronchi by contracting connective tissue in the surrounding fibroid lung. This obviously postulates the existence of pleural adhesion, which is not invariably present. While this must be admitted as a possible contributory factor, its importance is certainly less than that of the preceding ones.

Congenital bronchiectasis is a pathological rarity. It is usually unilateral, and the bronchi involved are of small size, although in some cases the lung may show a large central cavity, with smaller spaces around it. Bronchiol-ectasis is also more of pathological than of clinical interest. It occurs chiefly in children, as the result of acute broncho-pneumonic processes. It is said sometimes to follow influenza and possibly tuberculosis. The lung has a peculiar spongy appearance, to which the name "honeycomb" has been applied.

Bronchiectasis of the larger tubes may be either cylindrical or saccular. In the former condition several of the bronchi are more or less uniformly dilated, and when opened out they appear like the fingers of a glove. Sometimes the dilatations are fusiform, at others they show abeaded arrangement, described as moniliform. These forces of dilatation are usually associated with emphysema and chronic bronchitis. Saccular bronchiectasis is generally localised and may be found in any part of the lung, but is most common in the lower lobes and near the base. This is partly due to the fact that the antecedent processes fall with special stress on the basis of the lung, and partly to the influence of gravity in leading to retention of secretions in these parts. Although it may be unilateral in origin, it often spreads and may involve both bases or even all the lobes. There may be one large irregular cavity, or a series of smaller globular dilatations involving the whole or part of the walls of one or more bronchi. The cavities are usually filled with the foetid secretion, to be described under expectoration. When this is washed away the walls are found to be thin, smooth and formed of thinned-out mucous membrane. In places this may have ulcerated, owing to the tryptic action of the secretion, and the lung tissue is thus exposed. An abscess may then form, and an aneurysm sometimes develops, as in a tuberculous cavity. The openings of the smaller bronchi, derived from what diluted, can often be recognised in its walls. In doubtful cases the histological demonstration of cartilage and muscle in the walls establishes the bronchial origin of a cavity. The surrounding lung tissue is usually airless and fibroid, and sometimes is almost of leathery consistence. Occasionally, however, it is emphysematous, congested or pneumonic. In the great majority of cases there is a dense pleural adhesion over the area of lung involved.

Other morbid conditions found post mortem include lardaceous disease, gangrene of the lung, empyema, pyo-pneumothorax, suppurative pericarditis and cerebral abscess. Owing to the obstruction of the pulmonary circulation which may result, engorgement and dilatation of the right side of the heart, tricuspid regurgitation and the results of systematic venous stasis are often found.

Symptoms.—The onset is usually insidious the symptoms developing

during the course, or as a sequel, of one of the acute or chronic affections mentioned above. In some few cases, however, they develop rapidly in patients previously in good health. This is particularly the case where bronchiectasis results from an inhaled foreign body, and a rapid onset should lead to the suspicion of this. The cough in well-developed cases is somewhat characteristic and occurs in paroxysms. These are frequently induced by change of posture—for example, bending forward, or lying down. They occur with special frequency on rising, and are usually associated with the expectoration of large quantities of sputum, due to the overflow of the secretion, accumulated in the cavities during the night, into a sensitive or relatively healthy bronchus, which excites cough reflexly. They also occur on retiring to bed and at long intervals during the day. The sputum frequently amounts to as much as 20 or 30 ounces in the 24 hours. It is generally extremely foetid, although in the earlier stages it is not invariable. The patient's breath is often also malodorous, and the stench may pervade the room or even the house in which he lives, although it is not persistent. The patient is himself much distressed by the unpleasant character of the sputum, of which he is, as a rule, acutely conscious. On standing in a glass vessel it can be said to settle into three layers— a surface scum of light frothy mucus, an intermediate stratum of thin, turbid, greenish fluid, and a deep layer of brownish colour consisting of muco-pus, bacteria, and putrefactive products, including foul-smelling organic acids. Foetid yellow bodies called Dittrich's plugs can usually be found in the deep layer. Elastic tissue is only present when erosion of the wall has occurred. Hæmoptysis is not infrequent, and may occasionally be fatal. Dyspnoea is not, as a rule, apparent unless the condition is widespread, or unless the pulmonary or cardiac complications are present. The general condition of the patient is at first but little affected, and there may be no fever for long periods. As the disease progresses, lassitude, anorexia and some wasting slowly develop, while bouts of fever occur, due to retained secretions or to some complication.

Physical signs vary with the extent and degree of dilatation, and also with the amount of secretion present. In the early stages there is at most slight dullness at one base, with diminished air entry, peculiar ticky, "leathery" râles, and diminished vocal resonance. When bronchiectasis is well developed the signs are almost characteristic. The patient may appear well nourished and of good colour, although on cold days, especially in children, duskiness or cyanosis is often noticeable. There is well-marked clubbing of the fingers, generally of drum-stick character, and pulmonary osteo-arthritis, involving many joints, sometimes develops. There may be localised flattening or retraction of the chest wall over the affected area, with diminished movement, and the heart is drawn over to this side. The remaining signs vary with the state of the cavity. If this is full, there is diminished vocal fremitus, dullness and weak or absent breath sounds and voice sounds. If the cavity is empty or partly empty, the vocal fremitus is increased, the percussion note is boxy or dull, while the breath sounds are bronchial or cavernous. Adventitious sounds are then generally audible, the most characteristic being sharp metallic or "leathery" râles. Bronchophony and pectoriloquy are marked, and not infrequently the "veiled puff" of Skoda can be heard. Signs of bronchitis are often apparent in the adjacent lung tissues; compensatory emphysema may be demonstrable in the un-

affected parts of the lung, and on the opposite side. X-ray examination serves to define the extent of the disease, the degree of fibrosis, and the presence of the cavities.

Complications and Sequelæ.—The chief pulmonary complications are septic broncho-pneumonia, gangrene and abscess. The pleura may become involved, giving rise to dry pleurisy, which sometimes progresses to empyema and rarely to pyo-pneumothorax, while the other cases of pleural adhesion and contraction result. Septic pericarditis may develop and prove fatal. Septicæmia and pyæmia sometimes occur as terminal results. Cerebral abscess constitutes a serious and somewhat common complication, and may be found in the frontal, parietal or temporal regions, the cerebellum or cord. Occasionally multiple abscesses form. Lardaceous disease sometimes develops especially in the liver, kidneys and intestines.

Course.—This is progressive, but is often slow unless fever or complications develop, though the morbid process may eventually involve the other lung. The sputum at first may be simply purulent, then becomes unpleasant and finally foetid. The disease may start in childhood and not lead to death until well on in adult life. The course is slower in cases due to bronchitis and fibroid lung conditions than in those due to foreign bodies, new-growths or aneurysm.

Diagnosis.—In well-developed basic cases this is, as a rule, easy. The history of cough, influenced by posture and associated with copious sputum, is suggestive, especially when variable physical signs are observed. The development of the characteristic sputum with these signs renders the diagnosis almost certain and the X-Rays usually serves to confirm. Radiological investigation after an intra-tracheal injection of 20 c.c. of lipiodol, through the crico-thyroid membrane or between two rings of the trachea, under local anaesthesia, or with care directly between the vocal cords, has greatly facilitated the diagnosis of bronchiectasis. Recently Franklin has recommended the nasal route for the introduction of the lipiodol. One nostril, the oro-pharynx and the larynx are cocaineised, then a gum-elastic catheter is passed along the floor of the nose into the larynx. Some cocaine is injected down the catheter and then the lipiodol follows. An attempt should be made to direct the lipiodol towards the affected side by turning the patient towards that side. The injection should be carried out in the X-Ray room and the patient instructed to restrain cough if possible until the films have been taken. The pictures obtained are strikingly characteristic and of great value. In cases with less characteristic symptoms and signs the distinction has to be made from chronic bronchitis, especially the foetid variety, pulmonary tuberculosis, gangrene or abscess of the lung, and foetid empyema. The distinction from chronic bronchitis may be difficult, especially in the early stages when the sputum is not foetid, but the paroxysmal cough, the copious expectoration with signs including bronchial breathing and sticky rales at the base, may be strongly suggestive. In foetid bronchitis the foetid sputum is not constant, and the cough and sputum may occur only during exacerbations of the bronchitis. Pulmonary tuberculosis may give rise to difficulty, particularly in cases of apical bronchiectasis. Repeated examinations for tubercle bacilli and also for elastic tissue in the sputum should be made. The history, the mode of spread, and X-Ray examination may all assist. It should be remembered that the two conditions may coexist, and this may be suspected in some cases of fibroid tuberculosis with basic ex-

cavation. Abscess and gangrene of the lung have a more acute onset and course, but the chronic cavities left by these conditions may give rise to difficulty. In such cases the history may be an important aid in diagnosis. In foetid empyema rupturing through the lung, particularly when of interlobar origin, the patient is generally acutely ill, there may be a history of pleurisy at the onset and possibly some evidence of mediastinal pressure or cardiac displacement.

Prognosis.—This varies with the cause. If due to aneurysm or growth, the duration is determined by these conditions. Bronchiectasis induced by a foreign body is generally permanent, even when the latter is removed, but it is not progressive. If the foreign body is not removed, complications generally supervene, and the course may be rapid. In bronchiectasis due to bronchial or pulmonary disease the course may extend into years, particularly if treatment is followed strictly, but sooner or later toxæmia and general or local complications supervene, with the result that the duration of life is inevitably considerably shortened.

Treatment.—Prophylactic treatment in cases of chronic bronchitis, delayed resolution in pneumonia and other conditions tending to fibrosis should be carried out. This comprises respiratory exercises, climatic treatment, inhalations and vaccines.

The medical treatment of bronchiectasis consists in measures to promote it. The first of these involves a careful mode of life, adequate rest and the general health and well-being of the patient, to secure efficient emptying of the cavity, and to lessen or control the putrefactive processes occurring in change, a good and digestive diet, and medicine such as cod-liver oil, iron, quinine, strychnine or arsenic. The evacuation of the cavity may be promoted by postural methods, such as bending over the edge of the bed or stooping forwards. Expectorants, especially of antiseptic character, may be given, such as creosote, terebene, tar preparations, balsam of tolu or Peru, compound tincture of benzoin or the benzoates. If the sputum is tenacious, or if more bronchitis coexists, iodides and alkalis may be given in an ordinary expectorant mixture. To lessen the fœtor, creosote is most frequently given in perles of 3 to 5 minims three times a day after food, or in an emulsion with cod-liver oil. Guaiacol carbonate and other creosote derivatives may also be tried. *Syrupus alii*, in 1-drachm doses, is sometimes given, and is of value; but it is not always well tolerated by patients on account of its taste and tendency to repeat. Although these drugs are helpful, the amount of antiseptic reaching the cavity by the blood must necessarily be small. Attempts to secure most direct application by intratracheal injection and by inhalation have been made. For the former 1 drachm of a mixture of olive oil 88 parts, guaiacol 2 parts, and menthol 10 parts is injected down the trachea by a special syringe, the nozzle of which is slightly inclined towards the affected side. Care must be taken to do this with the aid of a laryngeal mirror to ensure that none of the solution touches the larynx. Another solution used is 1 part each of creosote, menthol and thymol in 10 parts of olive oil.

For inhalation purposes, solutions of volatile antiseptics are employed on a Burney-Yeo mask, such as creosote, terebene, menthol or eucalyptol in spirits of chloroform. The mask may be worn almost continuously or at intervals during the day. The creosote vapour bath is, however, the most

satisfactory form of inhalation treatment, and is of great value. This should be given in a concrete-floored room without furniture. The patient is covered with a smock, the eyes are protected by closely-fitting goggles, and the nostrils by cotton wool plugs. A small quantity of creosote is heated in a metal dish, on a tripod over a spirit lamp. When the patient inhales the vapour, which quickly fills the room, violent cough is excited and the cavity is emptied. The ensuing deep inspirations carry down creosote-laden air into the air passages. The baths should be at first given on alternate days and last from 10 to 15 minutes. When the patient becomes accustomed to them, they may be given daily for half an hour or longer. The results are often strikingly beneficial. Vaccines made from the predominant organisms found in the sputum have been given with benefit in some cases. Surgical treatment is now more often employed than formerly. Repeated washing-out through a bronchoscope, at weekly intervals, is often helpful, giving comfort to the patient by diminishing the amount of sputum, and lessening or abolishing its foetor. The actual drainage of the bronchiectasis surgically is only practicable if the cavity is a single one, and it involves the risks of a permanent fistula and of cerebral abscess. Induction of artificial pneumothorax is sometimes of value, especially in early cases, in which it may be strikingly successful. Unfortunately it is often impracticable, owing to adhesions, and even in cases in which it is carried out, the beneficial effect only persists as a rule while the collapse is maintained. Thoracoplasty may also give excellent results in cases in which collapse by artificial pneumothorax is not practicable. It is, however, only to be considered in strictly unilateral cases. This is usually carried out in two stages, with an interval between them. A sufficient amount of a number of ribs is removed to allow the chest-wall to fall in and permit the lung to collapse and fibrose, thus allowing the bronchiectatic cavities to empty and contract. Ligature of the branch of the pulmonary artery going to the lower lobe has been performed in some cases. Exairexis (evulsion) of the phrenic nerve has also proved useful, especially in localised basal cases and in those secondary to abscess of the lung. Lobectomy or removal of the affected lobe has also been recommended, but the mortality of this operation is at present considerable, though lessening with improving technique.

INJURY

External trauma applied to the chest-wall may cause rupture of a main bronchus. This is especially liable to occur after severe crushing accidents. One or other of the main bronchi may be completely severed from the trachea. The chief clinical feature presented in such a case is emphysema of the neck and upper portion of the chest wall. Death usually ensues in 2 to 3 days.

G. E. BEAUMONT.

DISEASES OF THE LUNGS

HYPERÆMIA AND CEDEMA

Hyperæmia of the lungs may be either active or passive. In the former there is an increased supply of arterial blood through the pulmonary and

bronchial arterioles. In passive hyperæmia there is engorgement of the pulmonary venous radicles and capillaries. With both forms there is frequently cedema, due to the exudation of serous fluid into the lung alveoli. The term "congestion" is sometimes employed as an alternative to hyperæmia, but owing to its erroneous popular use it is best avoided.

(a) ACTIVE HYPERÆMIA

Ætiology.—This may occur in association with any acute inflammatory process affecting the bronchi, lungs or pleura. It sometimes results from the inhalation of pulmonary or bronchial irritants, such as poisonous gases or heated air. Severe muscular exertion and exposure to extreme cold are described as causes, but the former at least is doubtful. An important variety is that known as *collateral* or *fluxionary hyperæmia*, which occurs when there is obstruction to the circulation in the whole or part of one lung, from conditions such as a large or rapidly developing pleural effusion, an extensive and spreading pneumonia, or in association with pneumothorax. This may develop in the sound lung, or in the unaffected parts of that diseased. A primary form of acute hyperæmia, the "maladie de Woillez" has been recognised by French authors, but this is generally regarded as a mild or abortive pneumonia.

The clinical manifestations of acute hyperæmia are merged in those of the processes with which it is associated, and therefore do not need separate description.

(b) PASSIVE HYPERÆMIA

Ætiology.—Passive hyperæmia may be produced by (1) conditions impeding the venous return from the lungs; (2) those leading to increased resistance to the passage of blood through the pulmonary capillaries, and (3) failure of the driving power of the right ventricle. The commonest causes of impeded return are left-sided heart lesions causing overfilling of, and increased pressure in the left auricle. In mitral stenosis it may occur early and sometimes almost acutely, but aortic and myocardial lesions also lead to it, when the left ventricle fails and the mitral valve yields. Direct obstruction of the pulmonary veins sometimes results from external pressure by aneurysm, mediastinal tumour or enlarged bronchial glands, or from obstruction of the lumen by thrombosis. The passage of blood through the pulmonary capillaries may be impeded by emphysema, chronic bronchitis, pulmonary tuberculosis and fibrosis of the lungs. Failure of the right ventricle occurs in the late stages of right-sided heart lesions, such as tricuspid regurgitation, and as a late sequel of left-sided failure.

Passive hyperæmia is obviously in the main dependent on mechanical factors; it is not surprising, therefore, that gravity seems to play a part in the localisation of its effects, which are usually most marked in the bases or most dependent parts of the lungs. In bedridden, enfeebled or old patients, particularly if myocardial weakness or degeneration coexists, this factor becomes of great importance. Not infrequently some degree of cedema of the bases develops, and the condition is then called hypostatic congestion. If such an area becomes infected the resulting process is known as hypostatic pneumonia. Basal hyperæmia and cedema of the hypostatic type also result

from toxæmia due to diseases such as enteric fever, from poisoning by drugs such as morphine, and as a terminal event in many cerebral lesions causing increased intracranial pressure.

Pathology.—The pulmonary veins and capillaries are engorged, with the result that the lung is darker in colour and heavier, while the alveolar walls and septa are swollen. If the condition persists, for some time, pigment derived from the hæmoglobin of red corpuscles escaping by diapedesis is deposited in the epithelium of the alveoli and in the fibroblasts in the inter-alveolar septa. In long-standing cases the lung is firmer than normal and brownish-red in colour, a condition described as *brown induration*. If any degree of œdema is present, serous fluid is found in the alveoli on post-mortem examination, and on section of the lung frothy serous fluid exudes, which may contain some of the pigmented alveolar cells, constituting what are called “cardiac cells.” Although congested and œdematous lung is heavier than normal, it usually floats in water.

Symptoms.—In slight degrees of hyperæmia these may be absent or negligible. In more advanced cases, they are those resulting from the impeded circulation through the lungs and the deficient aeration which this entails. Dyspnœa is the most prominent symptom, and it is generally a measure of the degree of hyperæmia. It is markedly increased by exertion of any kind, and in extreme degrees it is distressing and eventually alarming. It may be inspiratory or expiratory in type, and in the latter case it is sometimes described as cardiac asthma. In severe cases there is usually orthopnœa. Cough is almost invariably present, and there is usually some expectoration of frothy fluid, which may be blood-stained. The pigmented cells referred to above as “cardiac cells” may be found in it. Cyanosis is common and indicates the degree of deficient aeration. This may be associated with distension of the jugular veins, and there is often obvious distress. As in other forms of cyanosis there is usually some increase in the number of red corpuscles. The vocal fremitus at the bases may be diminished, the percussion note impaired, the breath-sounds weak and accompanied by rhonchi, crepitations or bubbling râles, although these signs are for the most part due to the associated œdema. In addition, the signs of the primary condition in the lungs or heart will be apparent.

Complications.—Pulmonary œdema and infarction are the chief complications.

Course.—If the venous engorgement cannot be removed, it usually tends to become progressively worse, whereas when it results from temporary cardiac embarrassment, recovery is usually complete as soon as the heart function is restored.

Diagnosis.—This condition has to be distinguished from (1) chronic bronchitis, in which case there may be some rise of temperature and the physical signs are more variable and more disseminated; (2) infarction, in which pain and hæmoptysis of sudden onset are the rule.

Prognosis.—This is so entirely dependent upon the nature and degree of the condition responsible for the engorgement that no general rule can be formulated.

Treatment.—In elderly patients, or those likely to be confined to bed for long periods, attention should be directed to the decubitus. This should be changed frequently, and if possible the patient should be permitted to sit

up or to get into a chair, and encouraged to take a few deep breaths several times during the day. If the hyperæmia is associated with cyanosis and engorgement of the right heart, bleeding to the extent of 8 to 12 ounces may be helpful. If this is not practicable, the application of 6 leeches over the liver, or dry cupping of the bases of the lungs may be tried. Free purgation and the administration of diuretics may also help indirectly to relieve the engorgement. In cases associated with cardiac failure, the administration of cardiac tonics, such as digitalis, strophanthus or squills, the injection of strychnine, or camphor in oil may all be of assistance. Moderate hæmoptysis should not be checked, and cough, if effective, may be promoted by suitable expectorants. In cardiac cases a "régime lactée" or strict milk diet is advocated by some French physicians.

(c) ACUTE OR HYPERACUTE PULMONARY ŒDEMA

In this condition flooding of the alveoli with the serous exudate from the pulmonary capillaries occurs with great rapidity.

Ætiology.—It is more commonly met with after the age of 40 than before, although cases have been recorded in children. It is considerably more frequent in the female than in the male sex. Arterial disease and hypertension are the most common antecedents, but acute or chronic renal disease and pregnancy may all act as predisposing factors. It sometimes occurs in diabetes. The actual exciting cause is often obscure, and probably varies in different cases. A heavy meal, an epileptic fit, or the administration of an anæsthetic may be the immediate cause in those predisposed. In other cases it may be a manifestation of angio-neurotic œdema. Sometimes paracentesis of a pleural effusion is quickly followed by œdema, no doubt as a result of a collateral hyperæmia. It has occurred after "gassing" by chlorine. In diabetes the lipæmic condition which sometimes occurs has been suggested as the determining factor, possibly causing multiple fat embolism. In some cases dissociation of the action of the two ventricles has been supposed to be the cause, the right contracting forcibly while the left is in an enfeebled or asystolic condition. In support of this contention may be adduced the fact that acute pulmonary œdema has been observed after rupture of the chordæ tendinæ of the mitral valve.

Pathology.—The alveoli are found to be flooded with a thin serous exudate. The lungs are heavier than normal, sodden, and on squeezing exude large quantities of greyish-yellow or pinkish fluid. Frothy fluid of similar character is found in the bronchi and even in the trachea and nasopharynx in hyperacute cases.

Symptoms.—The onset is sudden, and generally occurs when the patient is lying down, hence being most frequently observed at night. The patient awakes with intense dyspnœa, and a sense of suffocation, then frequently rolls or rushes about in the endeavour to breathe, even clutching at the throat. Cyanosis is present, and the aspect is one of anxiety and alarm. Frothy fluid may soon stream from mouth and nose, or be brought up in great gulps. The chest movements are hurried, and the accessory respiratory muscles are in violent action. Vocal fremitus is diminished over the lower lobes. The percussion note soon becomes impaired over the lungs, commencing at the bases. The breath-sounds are at first vesicular or harsh with

prolonged expiration, then become faint and may be obscured by bubbling râles or crepitations, audible all over the chest. Voice conduction is diminished.

Complications and Sequelæ.—Owing to its acute and rapid course, complications do not occur. Bronchitis may result as a sequela.

Course.—The malady usually lasts only minutes or hours. Unless it remits, or treatment affords relief, the patient rapidly becomes unconscious and death follows, the heart continuing to beat after respirations have ceased.

Diagnosis.—The affection is usually so characteristic that the diagnosis is obvious. In the more protracted cases the dyspnoea and the physical signs are not unlike those of acute suppurative bronchitis or suffocative catarrh and broncho-pneumonia; but in both of these there is some degree of fever and the expectoration is less copious, and when it occurs is usually of purulent or muco-purulent character. The nocturnal onset of œdema may suggest asthma; but the physical signs and the late and scanty expectoration in the latter suffice to distinguish it.

Prognosis.—The prognosis is always very grave; but prompt treatment has saved some cases. Death may occur in less than 10 minutes, or be delayed for 24 or 48 hours. In the angio-neurotic type repeated attacks may occur.

Treatment.—The most successful treatment is the immediate subcutaneous injection of gr. $\frac{1}{4}$ morphine. Good results have also followed the injection of gr. $\frac{1}{100}$ atropine sulphate hypodermically. These are often given together. Oxygen inhalation will probably not be tolerated owing to the restlessness, and is of doubtful utility. Prompt venesection has been recommended, and should be tried if possible; but its value has not been established.

(d) CHRONIC PULMONARY ŒDEMA

This is usually the sequel of chronic passive hyperæmia, and the causes and symptoms are those of that condition. It may also occur in chronic renal disease. In marked degrees of œdema, however, the signs may closely simulate those of pleural effusion, save for the displacement of the cardiac impulse. It is important to remember that some degree of hydrothorax may occur as a complication, and increase the difficulty in diagnosis.

INFARCTION OF THE LUNGS

Infarction of the lungs or "pulmonary apoplexy" results when a branch of the pulmonary artery becomes occluded by embolism or thrombosis.

Ætiology.—*Embolic forms.*—The obstructing plug may originate in any part of the systemic venous system, in the right side of the heart or on its valves or in the pulmonary artery itself. The commonest peripheral cause of embolism is detachment of a thrombus in cases of thrombo-phlebitis. This may occur in the veins of the lower extremity, or in those of the uterus after childbirth. Thrombosis with embolic detachment may also develop in prolonged or wasting diseases, such as enteric fever, tuberculosis and cancer; in acute processes, such as influenza, septicæmia and pyæmia; and in localised septic lesions, such as otitis. Pulmonary embolism is not infrequently

observed after abdominal or pelvic operations, and after the radical cure of hernia or hæmorrhoids.

Intracardiac thrombi, from the right auricle or ventricle, becoming detached, lead to embolism, and this occurs especially in cases of right-sided heart failure secondary to left-sided valve lesions. Vegetations forming on the tricuspid or pulmonary valves in septic endocarditis on detachment produce pulmonary infarction. Rarer causes are fat embolism after injury to bone or to a fatty liver, the entry of pieces of new-growth or hydatid daughter-cysts into systemic veins, and even air embolism.

The exciting cause of embolism is not infrequently sudden movement or strain leading to detachment of a thrombus or vegetations.

Thrombotic forms.—Thrombosis occurs as a secondary process around pulmonary emboli; but it is probable that some cases of infarction are due to a primary thrombosis. This condition may be produced by some acute or chronic pulmonary disease, such as gangrene, tuberculosis and fibrosis, and by atheroma of the pulmonary artery. Any process leading to chronic venous hyperæmia may also cause it. A rare cause is thrombo-phlebitis migrans.

Pathology.—Although the pulmonary arteries are not strictly speaking end arteries, since there is some degree of anastomosis between them and the bronchial arterioles, yet the result of their obstruction is to produce infarcts comparable with those in other organs. The origin of the blood in the obstructed area has been much discussed. Cohnheim regarded it as the result of regurgitation from the veins, a view subsequently disproved, since the infarct is hæmorrhagic even when the veins are also obstructed. It is now regarded as due to influx from the anastomosing bronchial capillaries into the pulmonary capillaries, and the escape of this blood from the latter owing to their altered nutrition. It is generally accepted that embolism is much more common than thrombosis. It has been suggested that some infarcts are not obstructive, but are the result of hæmorrhage *per rhexin* in cases of extreme passive hyperæmia, and that the shape is due to the alveolar distribution of the bronchial area affected. If a large embolus has caused sudden death, it will be found arrested at the bifurcation of a large branch of the pulmonary artery, or even in one of the main divisions of that vessel. In such cases there has not been time for pulmonary changes to occur, and the chief post-mortem condition found is engorgement of the right side of the heart.

In post-mortem examination of cases where smaller emboli have led to infarction, the infarcts are usually found in the lower lobes, more commonly in the right lung. They extend to the surface in the majority of cases, and can be seen before section as slightly raised, dark red areas, with the overlying pleura a little roughened from inflammatory exudate. They feel hard and firm, and on section are typically wedge-shaped, with the base on the surface and the apex centrally placed. In the rare deep-seated infarcts a spheroidal form is the rule. When recent, an infarct is dark red in colour, and suggests hæmorrhage with clot formation, hence the term "pulmonary apoplexy." In some cases infarcts have a purplish hue, and are said to resemble the colour of damson cheese; later they change to brownish-red. Infarcted areas sink in water. There may be a single large infarct almost occupying one lobe, sometimes only a small one, or several of varying size

and age scattered throughout the lungs. In some cases a fortunate section may reveal the embolus with its ensheathing thrombus, but sometimes a thrombus only is found. Microscopically, the alveoli and finer bronchioles are filled with red blood corpuscles, and there is a sharp delimitation from the healthy lung. If the embolus is infective, suppuration occurs, and abscess or empyema ensues.

Symptoms.—If a large embolus blocks one of the main divisions of the pulmonary artery, there is sudden intense dyspnoea, pain in the chest, distress, cyanosis, and rapid unconsciousness, death resulting in a few minutes from asphyxia. In other cases the patient gives a short cry, and falls unconscious, death occurring almost immediately from syncope. In some cases unconsciousness develops so rapidly, and the respiratory symptoms are so little apparent, that a cerebral vascular lesion may be suspected. On the other hand, life may be maintained for several minutes or even hours, the patient being unconscious or in acute distress and anxiety with urgent dyspnoea, lividity and cyanosis. Respiration is deep and laboured, but fails to give relief to the sense of suffocation. In such cases also, death may result eventually from asphyxia or syncope, or the patient may slowly recover. In less severe forms, such as occur in cardiac and in some post-operative cases, there is sudden pain with difficulty in breathing, followed in a few hours or in a day or two by cough with hæmoptysis or by the expectoration of deeply blood-stained mucus persisting for some days, and slowly clearing up. If the embolus is infective, fever, often of hectic type, results, sometimes delayed for a day or more.

In the severe cases there is cyanosis, distension of the veins of the neck, acute anxiety with exophthalmos and cold, clammy skin. The only physical signs apparent are the deep, laboured breathing, the harsh breath-sounds, and the evidence of cardiac embarrassment with feeble, failing pulse.

In less severe cases the signs are also not characteristic. There are evidences of cyanosis and distress of less urgent character, possibly some limitation of movement on the affected side, increase of vocal fremitus, localised dullness, with weak or absent breath-sounds, and sometimes a pleural rub. In some cases definite bronchial or tubular breath-sounds may be audible. A few fine râles are sometimes present in the adjacent lung areas.

Complications and Sequelæ.—Localised dry pleurisy is almost invariably present. With infective emboli, abscess or gangrene, and later empyema may result. In organisation an infarct leads to a localised area of fibrosis.

Course.—As already described, death may occur from asphyxia or syncope in the course of a few minutes or hours, although recovery occurs in some very severe cases. In the less severe forms, after the initial urgent symptoms have passed off, recovery is often rapid and uneventful, save for pain, cough and bloodstained expectoration.

Diagnosis.—The dramatic onset, the history and the associated lesions of the veins or heart render diagnosis easy as a rule; but it may be necessary to eliminate other causes of hæmoptysis, notably pulmonary tuberculosis and chronic venous hyperæmia.

Prognosis.—This depends largely upon the initial shock. The prognosis is very grave when the patient rapidly becomes unconscious. As there is less likelihood of sepsis in cases due to cardiac lesions than in those due to localised venous thrombosis, the prognosis is rather better in the former;

1142 DISEASES OF THE RESPIRATORY SYSTEM

but, on the other hand, organisation of a clot in a vein may completely remove the source of the emboli, while the source often persists when they are derived from the heart.

Treatment.—The coagulability of the blood may be lowered by the administration of 30 grains of sodium citrate three times daily. This is a wise prophylactic measure in prolonged illness, especially when a milk régime is being enforced. When thrombosis has occurred in a peripheral vein, such as in the leg, the affected limb should be immobilised until organisation of the clot has taken place. Morphine is useful in quieting a patient if there is much mental distress when a pulmonary infarct forms; but usually the patient is collapsed and stimulant measures are indicated. An injection of morphine gr. $\frac{1}{2}$, atropine gr. $\frac{1}{160}$, and strychnine gr. $\frac{1}{30}$ is found of value in some cases. If there is dyspnoea oxygen should be administered. Venesection to the extent of 10 or 12 ounces may be tried in cases where there is marked lividity with a forcibly acting heart. Hæmoptysis, when it occurs, should not be checked. Pain may be relieved by leeches, cupping or by application of iodine. In cases with heart failure the appropriate treatment by cardiac tonics should be administered.

COLLAPSE OF THE LUNGS

In collapse of the lungs the alveoli are completely or partly devoid of air. The condition may be congenital, and due to non-expansion of the lung, when it is referred to as atelectasis. On the other hand, collapse may be the result of removal of the air from lung tissue previously expanded, when it is called apneumotosis or acquired collapse. The three terms—collapse, atelectasis and apneumotosis—are, however, used as synonyms by many writers.

ATELECTASIS OR CONGENITAL COLLAPSE

Ætiology.—This condition occurs in still-born and in premature infants, and probably persists to some degree for weeks or even months in weakly children. It may result from immaturity or from weakness of the inspiratory muscles, and from obstruction of the air passages by mucus and meconium. It may be a consequence of disease, such as congenital syphilis or lesions and developmental defects of the nervous system.

Pathology.—Atelectasis is due to failure of the respiratory mechanism to draw air into the alveoli and expand them, as occurs normally with the first few inspiratory efforts of the newborn infant.

Atelectatic lungs are solid, airless and small. They are usually described as presenting appearances similar to those of adult liver as regards colour and consistence. In partial atelectasis the lung appears mottled, and small expanded areas of pinkish colour may project from the surface. The condition is chiefly of medico-legal and pathological interest.

APNEUMOTOSIS OR ACQUIRED COLLAPSE

Collapse of previously expanded lung may be active or passive, the former being due to active shrinking of the lung owing to defects in the inspiratory

musculature, the latter to conditions disturbing the pressure relations within the thorax.

1. ACTIVE PULMONARY COLLAPSE.

Synonyms.—Active Lobar Collapse ; Massive Collapse.

Ætiology.—This condition was first described by William Pasteur in 1890 in cases of diphtheria associated with paralysis of the diaphragm. In 1908 he pointed out that it occurred also as a sequel of operations, especially of those upon the abdominal organs, less frequently of those upon the neck and pelvis. It is highly probable that many post-operative lung conditions formerly recorded as pneumonia were in reality due to active collapse. It may also follow after injuries, such as those resulting from falls from a bicycle or a horse. During the Great War, when chest wounds were collected in special hospitals, it was found that massive collapse was not infrequently an important complication of penetrating and non-penetrating wounds of the chest. It was also noticed in some cases after severe wounds of the buttocks and pelvis.

Pathology.—The mechanism by which deflation results is obscure, and is the subject of controversy. Pasteur regards the condition in the diphtheritic cases as due to paralysis of the diaphragm through the phrenic nerves or their nuclei, and in the post-operative and traumatic cases as a consequence of reflex inhibition of this muscle. Briscoe, on experimental, pathological and clinical evidence discards Pasteur's explanation. He maintains that the deflation is caused by an exaggeration of the normal phenomena of breathing in the supine position, in which he states that the crural portion of the diaphragm alone contracts, the costal portion being in abeyance. In the supine position, with quiet breathing, deflation of the lower lobes occurs, and this is promoted by conditions of debility, toxæmia or operation. The clinical manifestations described by Pasteur are regarded by Briscoe as the result of superadded pleurisy, or of inflammation of the crura of the diaphragm.

Recently Boland and Sheret have put forward the suggestion that massive collapse is due to obstruction of the bronchi, followed by removal of the air in the corresponding lung areas by absorption into the blood stream. The obstruction is supposed to be due to increased secretion and the inhibition of the cough reflex.

Post mortem, the lower lobe of one lung is usually found to be deflated and retracted towards the spine. Sometimes the whole of one lung may be affected, or both lower lobes. The collapsed area is bluish-red, firm, does not crepitate and sinks in water. Pleurisy or pneumonic changes may be seen, and these are regarded by Pasteur as secondary to infection of the deflated lung, the resistance of which is lowered, and by Briscoe as the essential factor in the production of the symptoms. In massive collapse the heart and mediastinum are displaced towards the affected side, and the sound lung is often bulky and distended.

Symptoms.—The symptoms commonly commence within 24 or 48 hours of the injury or operation, although they may rarely be delayed for 5 to 7 days. The onset is generally sudden, with pain in the lower part of the thorax or behind the sternum. Severe dyspnoea quickly follows, and the patient appears dusky, cyanosed and alarmingly ill. Cough, with viscid mucoid expectoration, generally develops in a few hours. The latter may become copious and muco-purulent if pneumonic changes ensue. The pulse and

respirations are markedly increased in rate, and the temperature not infrequently rises to 103° F. Occasionally the onset is more gradual with pain and cough, and in some cases of wounds it may give rise to few symptoms and be discovered only on routine examination.

Examination of the chest shows diminished movement on the affected side, and often absence or reversal of epigastric excursion with respiration, whereas the movement on the other side may be exaggerated. In other respects the signs usually simulate those of lobar pneumonia. Over the collapsed lung the vocal fremitus is increased, the percussion note is dull, the breath-sounds are tubular, and bronchophony and whispering pectoriloquy are present; but as a rule there are no adventitious sounds, although occasionally rhonchi and a few fine râles may be heard. In some cases the breath sounds are very weak or almost absent, and voice conduction is diminished. Over the healthy lung, loud and harsh breathing is audible. The displacement of the cardiac impulse towards the collapsed lung is a point of cardinal importance. It is noteworthy that in certain cases of gunshot wounds of the chest the collapse affects the contra-lateral lung.

Complications and Sequelæ.—Bronchitis, lobar pneumonia, or pleurisy may occur as complications. There are usually no sequelæ, except that pleural adhesions may occur.

Course.—The course of the affection is rapid. After periods extending from 2 to 5 days the temperature falls to normal, the symptoms disappear, the lung quickly re-expands, the heart returns to its normal position, and there is complete recovery.

Diagnosis.—The most important conditions from which this malady has to be distinguished are lobar pneumonia, pulmonary embolism, pneumothorax and pleural effusion. The position of the cardiac impulse is often the deciding factor: in collapse it is displaced towards the lung involved, in pleural effusion and pneumothorax it moves away from the affected side, whereas in lobar pneumonia there is usually no cardiac displacement, although there may be dilatation. Labial herpes and blood-stained expectoration are frequently seen in pneumonia, but not in collapse. When in right-sided collapse there is marked distension of the left lung with obliteration of the normal cardiac dullness, the signs superficially resemble those of a left-sided pneumothorax; but with careful examination no such error should be made. The distinction from pulmonary embolism may be difficult at first, but the localisation of the signs, and the blood-stained expectoration, may give useful indications.

Treatment.—*Prophylaxis.*—The administration of morphine and atropine before the anæsthetic, propping up of the patient in bed as soon as possible after it, and the insistence upon periodic deep breaths are useful measures in preventing the onset of lobar collapse. When the "collapse attack" develops oxygen should be administered and pain relieved by local applications, such as leeches or poultices, or by an injection of morphine, atropine and strychnine. Expectorants may be given if the cough is ineffective, and cardiac tonics, such as digitalis, strophanthus and caffeine if there is much cardiac embarrassment. Injections of strychnine or camphor in oil are useful if the patient is collapsed at the onset.

2. PASSIVE PULMONARY COLLAPSE.—This form of collapse may affect the whole of one lung, or be confined to one lobe or to groups of lobules.

Ætiology.—Total collapse is generally the result of pleural effusion, empyema, pneumothorax or obstruction of a main bronchus. In a large effusion and in pneumothorax collapse is complete, unless the shrinkage is prevented by adhesions. In a smaller effusion, the process may be limited to the lower parts of the lung. Other causes of lobar or partial lobar collapse are conditions leading to complete obstruction of a main bronchial division, particularly new-growth, aneurysm or foreign body. It also occurs in aged or bedridden patients, or in those with enfeebled inspiratory muscles, when prolonged fever has enforced a dorsal decubitus. Abdominal distension from tympanites or ascites can also cause collapse of the bases of the lungs.

Lobular collapse results from any condition impeding the air entry to the smaller bronchi or bronchioles, such as bronchitis, broncho-pneumonia, pulmonary tuberculosis, whooping-cough and diphtheria. Obstruction of the naso-pharynx by enlarged tonsils and adenoids may cause partial collapse, especially in the upper lobes.

Pathology.—The deflation of the lung area may be produced in three ways—(1) By complete obstruction to the air from blocking of a bronchus or bronchiole, the residual air being absorbed; (2) by enfeeblement of the inspiratory mechanism similar to the process in active collapse; and (3) by disturbance of the intrapleural pressure by fluid or air, the lung at first contracting in virtue of its elasticity until the intrapleural pressure becomes equal to that of the atmosphere, when any further accumulation of fluid or air causes positive pressure and compression of the collapsed lung. It is said that a plug of mucus in a bronchus may act as a ball valve, allowing the escape of air during expiration, and preventing its entry during inspiration. This view has now few adherents.

Post mortem, in complete or lobar collapse the appearances are similar to those in active collapse. In lobular collapse the deflated areas are contracted and depressed below the level of the healthy lung. They are dark red or slaty in colour, while the adjacent areas are pinkish and often emphysematous. The collapsed areas do not crepitate.

Symptoms.—Total collapse of the lung or of a lobe being usually a secondary process, the symptoms and signs are masked by those of the primary condition, such as pleural effusion, pneumothorax, growth or aneurysm. It can, however, usually be demonstrated by X-Ray examination, the collapsed lung being apparent as a fairly dense shadow lying alongside the vertebral bodies. Not infrequently, however, in pleural effusion definite tubular breath sounds, with bronchophony and pectoriloquy, may be audible in the relatively dull area above the level of the fluid posteriorly, and these signs are due to the collapsed lung. In aortic aneurysm, or less commonly in mediastinal, pulmonary and bronchial neoplasms, distinctive signs due to the local collapse may be apparent. These consist of slightly diminished movement of the corresponding part of the chest wall, with diminution of vocal fremitus and impairment of percussion note or actual dullness. Breath-sounds are weak, as a rule, but may be bronchial or tubular. Voice conduction is increased, and in incomplete collapse crepitations are often audible. The cardiac impulse may be displaced towards the affected side, but this is less apparent than in active collapse, and it is not infrequently displaced to the opposite side by the primary condition. Lobular collapse

gives rise to no symptoms which can be differentiated from those of the condition inducing it.

Complications and Course.—The lung usually re-expands wholly or in part when the condition causing collapse has been removed. Thus a lung that has been maintained continuously collapsed by artificial pneumothorax, with repeated refills for as long as 2 years or more, will re-expand when the gas in the pleural cavity is allowed to be absorbed. In chronic effusion, or in large or neglected empyemata, re-expansion may be incomplete, and some falling in of the chest wall results. Fibroid changes may occur in lung tissue which has been long collapsed.

Diagnosis.—This is frequently a matter of inference, owing to the nature of the primary disease. Valuable help may be afforded by X-Ray examination.

Treatment.—No special treatment apart from that of the condition causing the collapse is required. If a pleural effusion is slow to absorb, the necessity for paracentesis, to avoid too long collapse, may have to be considered.

HÆMOPTYSIS

It should be recognised that hæmoptysis is a symptom, not a disease. It is here considered separately because the accurate diagnosis of its origin is essential to its treatment, which differs widely in different conditions.

Definition.—The term hæmoptysis is arbitrarily restricted to the expectoration of blood, entering the air passages from structures below the larynx or from the larynx itself. When the blood is derived from the naso-pharynx or mouth it is sometimes described as spurious hæmoptysis.

Ætiology.—1. Pulmonary tuberculosis is the commonest cause, the blood being derived from an aneurysm in a pulmonary cavity, or from ulceration of a small vessel, or congestive processes around the early lesions.

2. Chronic venous congestion, particularly in mitral stenosis. These two conditions account for the majority of cases.

3. Inflammatory and destructive diseases of the lungs, air passages or pleura, such as pneumonia, broncho-pneumonia, especially the influenzal variety, abscess, gangrene and bronchiectasis with ulceration of the walls. A latent bronchiectasis without sputum may cause recurrent hæmoptysis (*forme hémoptoïque sèche*). Pneumokoniosis, streptotrichosis and ulceration of the larynx, trachea or bronchi from tuberculosis, gumma or new-growth may also be associated with hæmoptysis. Breaking down of a caseous or calcareous bronchial gland is a rare cause, as also is rupture of an empyema through a bronchus.

4. Infarction of the lung.

5. New-growths of the lung, bronchi or mediastinal glands.

6. An aortic aneurysm may cause hæmoptysis by "weeping" through an eroded bronchus, or by direct rupture, the latter being of course immediately fatal.

7. Traumatic causes.—Injury may cause hæmoptysis, by fractured ribs wounding the lung, by contusion and by breaking down of healed tuberculous lesions. Hæmoptysis occurs frequently in wounds of the chest, both pene-

trating and non-penetrating. A foreign body, such as a piece of shrapnel, may lie dormant for years, and then cause recurrent hæmoptysis.

8. **Certain abnormal blood conditions**, chiefly leukæmia, purpura, hæmophilia, scurvy and occasionally pernicious anæmia. Hæmoptysis occasionally occurs in the malignant specific fevers, especially small-pox and measles.

9. **Parasitic causes**, such as pulmonary distomatosis and spirochætosis, are common in Asia but rare in Europe. Hydatid disease of the lung may cause slight hæmorrhages.

10. **Vicarious menstruation**.—Some cases in women have been regarded as vicarious menstruation, and this view dates back to Hippocrates. It is probable, however, that most cases are to be explained as due to leakage from obscure pulmonary lesions.

11. Hæmoptysis occasionally occurs in apparently healthy persons. In some, with high systemic arterial tension, it is probable that the pulmonary arterial pressure is also raised, and the condition may be regarded as analogous to the epistaxis which occurs more commonly in such patients. Sometimes the hæmoptysis is due to leaking from an old arrested tuberculous lesion.

12. Rupture of an hepatic abscess or hydatid cyst through the diaphragm into a bronchus is an occasional cause.

Spurious hæmoptysis is usually due to staining of the saliva or the pharyngeal secretion with blood, generally derived from the gums, which are spongy and congested, often from early pyorrhœa. The condition is common in anæmic girls, and is, as a rule, observed in the morning. Hæmorrhage from an enlarged pharyngeal vein is often suggested as a cause, but is rarely seen. Hæmorrhage after tooth extraction, and staining of the mucus expectorated after epistaxis, are other causes of spurious hæmoptysis.

Pathology.—From the list of causes it might be inferred that the origin of the blood differs in different cases. It may come from the pulmonary or bronchial vessels in pulmonary tuberculosis and other lung or bronchial conditions, and also in chronic venous congestion or infarction. It may come from the thoracic aorta direct, or from some of its branches, in aneurysm and mediastinal new-growth, and from the hepatic vessels in abscess of the liver. In cases due to disease of the trachea and larynx it comes direct from the vessels supplying them.

On examination, the larynx, trachea and bronchi may contain clots, or blood-stained froth and mucus, and their walls may be stained in places. Dark reddish areas of lobular distribution, due to inhaled blood, may be seen in various parts of the lungs, particularly at the bases. Sometimes this may induce bronchitic changes, described as hæmoptoic bronchitis. Careful search in cases of profuse hæmoptysis will usually reveal the source of the hæmorrhage, and in pulmonary tuberculosis this is generally a ruptured aneurysmal dilatation in a cavity. The aneurysm may be small and escape notice unless many cuts are made into the lung.

Symptoms.—In hæmoptysis, the patient often experiences a tickling in the throat, followed by a gush into the mouth with a salt taste, and on expectoration notices blood. The alarm and anxiety this occasions lead to restlessness and rapid action of the heart. If the bleeding is profuse, cough is frequent, and large clots, together with liquid alkaline blood, may

be expectorated to the extent of 20 or 30 ounces in a few hours. The bleeding may cease temporarily, to recur at intervals for several days, until the patient becomes blanched, weak and syncopal, with rapid, weak pulse. In any profuse hæmoptysis, death may occur in a few minutes, either from asphyxia or syncope. In the former case, the blood, at first bright and arterial, is soon dark and frothed, while the patient becomes cyanosed and livid. In slighter degrees of hæmoptysis there may be only streaks, small clots or liquid blood mixed with ordinary sputum. After the actual bleeding has ceased, the sputum may be blood-stained for some days, owing to the expectoration of blood inhaled into other parts of the lungs. This can be recognised by its colour, which varies from dark red to brown, owing to the changes undergone by the pigment.

Diagnosis.—This involves two problems—first the differentiation from hæmatemesis and spurious hæmoptysis, and secondly the recognition of the cause of the hæmorrhage. If the patient is seen at the time of the bleeding the first of these is easy. The nature of the blood, and its association with cough and possibly with pulmonary or cardiac signs, are conclusive. When the diagnosis has to be made upon the history given by the patient or by friends it may be difficult, especially in the absence of physical signs.

In hæmatemesis there is frequently gastric pain and faintness before the vomiting, the blood is acid in reaction, dark in colour, even brown from acid hæmatin, and is sometimes mixed with food. The fact that in hæmoptysis blood may be swallowed and subsequently vomited increases the difficulty. Patients often give very dubious answers to questions as to whether the blood was coughed or vomited up. They should then be questioned as to whether sputum was brought up on the following day, and, if so, whether it was blood-stained. In cases of doubt the investigation of the pulmonary and abdominal physical signs, when the patient's condition permits, may decide the diagnosis.

Great caution should be exercised to exclude tuberculosis before making a diagnosis of "spurious hæmoptysis." Only when there are no pulmonary symptoms or signs, and when some obvious cause, such as anæmia or pyorrhœa, is found, is it safe to do so.

While distinguishing between the various causes of hæmoptysis it is well to regard and to treat it as due to pulmonary tuberculosis until some other cause is conclusively established. The sputum should be examined for tubercle bacilli on several occasions, the temperature recorded and the physical signs most carefully watched.

The presence of a valvular lesion, especially mitral stenosis with signs of pulmonary engorgement, may render the cause of hæmoptysis clear. When tuberculosis and cardiac disease can be excluded, a careful study of the history, the symptoms and signs, may throw light on the diagnosis or suggest some investigation which will serve to establish it, *e.g.* examination of the sputum for parasites and hydatid hooklets, the cytological examination of the blood and an X-Ray examination.

In other cases, as in bronchiectasis, abscess or gangrene, the history, the physical signs and the nature of the sputum are often characteristic.

In the latent or silent form of bronchiectasis (forme sèche), the condition may be revealed only by lipoidol injection.

Prognosis.—Apart from hæmoptysis, which is rapidly fatal, due to

aneurysm or pulmonary tuberculosis, the immediate prognosis in cases of pulmonary hæmorrhage is not unfavourable, even when it continues for days. The ultimate prognosis depends upon the cause.

Treatment.—This is so entirely dependent upon the cause and origin of the bleeding that reference should be made to the corresponding diseases.

EMPHYSEMA OF THE LUNGS

Emphysema of the lungs, or alveolar-ectasis, is a condition of distension of the alveoli; it is usually progressive and is associated with definite changes in the inter-alveolar walls. The following varieties are generally recognised—(1) Large-lunged or hypertrophic; (2) small-lunged or atrophic; (3) compensatory; (4) acute vesicular; and (5) acute interstitial emphysema. The last-named condition has no relation to true emphysema except in name, but will be described in this group for convenience.

1. LARGE-LUNGED OR HYPERTROPHIC EMPHYSEMA (SUBSTANTIVE OR IDIOPATHIC EMPHYSEMA)

This is a chronic affection and is usually bilateral.

Ætiology.—*Predisposing causes.*—It may occur at any age, even in childhood, but is most frequently seen in middle and late adult life. It is commoner in men than in women, probably because they are more exposed to the conditions inducing it. Although not strictly hereditary, it often shows a familial incidence. Certain occupations are credited with being concerned in its production, notably those involving violent or prolonged muscular effort with closed or partially closed glottis, such as blowing wind instruments and lifting heavy weights. Dusty occupations also favour its onset by leading to bronchitis and cough.

The common exciting cause seems to be the strain of prolonged and repeated cough, induced by chronic bronchitis, bronchiectasis, asthma, whooping-cough, cigarette smoke inhaling, and other causes of irritation of the upper air passages.

Pathology.—The pathogenesis of emphysema has been much debated and various explanations have been offered. (1) Primary degeneration theory. Villemin suggested that the essential lesion was a fatty degeneration of the alveolar walls, while Cohnheim believed that there was a congenital defect of the elastic tissue of the lung. (2) The inspiratory theory, first suggested by Laennec and developed by Gairdner, postulates the force of inspiration as the distending agent. (3) The expiratory theory, first enunciated by Mendelssohn, was independently brought forward and established by Jenner. The distension of the alveoli is regarded as due to the effect of forced expiration and cough. Jenner pointed out the special and early involvement of the apices, the anterior and lower margins of the lungs; in other words, the parts least supported by the thoracic cage. (4) Freund regarded the changes in the lungs as secondary to calcification of the costal cartilages, the chest becoming fixed in the inspiratory position and the lung permanently expanded in consequence. The expiratory explanation is now generally accepted, and emphysema is regarded as the result of increased intra-alveolar tension, due to violent expiratory efforts, acting on walls

weakened by congenital defects, by inflammatory processes or by toxic agents, such as alcohol (Nothnagel).

The characteristic conformation of the chest is usually apparent (see Symptoms), the costal cartilages are often calcified, and on opening the thorax post mortem, the lungs bulge instead of retracting, so that the pericardium may be almost completely obscured. They are pale in colour, even in town-dwellers, a condition called albinism of the lung by Virchow. They are soft and pit on pressure, and, as described by Laennec, give the sensation of a down pillow. The surface of the lung under the pleura shows a finely vesicular appearance, due to the distension of the alveoli, the vesicles often being nearly as large as pins' heads. Not infrequently large bullæ or blister-like protuberances, varying in size from a pea to a Spanish olive, may be seen projecting from the surface, particularly at the apices and margins. These bullæ when incised show fine fibrous bands crossing them, the remains of inter-alveolar walls and of atrophied blood vessels. It was formerly customary to refer to such cases as bullous or marginal emphysema and to describe those in which the dilatation is less obvious but more widely diffused as general emphysema; but the conditions are so commonly associated together in varying degrees that little is gained by so doing. On section the lungs are anæmic and dry, except at the bases, where there is frequently some œdema in advanced cases. The bronchi may show some general dilatation, although less commonly than might be expected from the close similarity of the causal factors of emphysema and bronchiectasis. Where bronchitis coexists, muco-pus can be squeezed from the cross-sections of these tubes. As pointed out by Fowler, pleural adhesion is relatively uncommon. The infundibula and alveoli are dilated, and the inter-alveolar walls are thin and atrophic, even disappearing wholly or in part. The distension and coalescence of adjacent alveoli result in the formation of bullæ. The calibre of the pulmonary capillaries is diminished by stretching of the alveolar walls, and where atrophy of the inter-alveolar septa occurs the capillaries are destroyed. These two processes result in a considerable diminution in the total aerating surface, and cause the dyspnœa and cyanosis characteristic of the disease. Moreover, the normal anastomoses between the terminal bronchial and pulmonary capillaries increase considerably, and some of the blood in the latter may therefore fail to reach the alveoli and so escape aeration. Atrophic changes in the elastic tissue have been described. In order to maintain the circulation through the diminished capillary area, the right ventricle hypertrophies and the resultant high blood-pressure sometimes induces atheroma of the pulmonary artery. Emphysema being a progressive lesion, and the defective aeration of the blood perhaps interfering with the nutrition of the heart muscle, cardiac failure eventually ensues, causing tricuspid regurgitation, engorgement of the right auricle, and the visceral effects of venous engorgement, such as "nutmeg" liver.

Symptoms.—Dyspnœa of varying degree is the most characteristic symptom. In uncomplicated cases of moderate extent it is only present on exertion, unless bronchitis coexists. In advanced emphysema, dyspnœa is marked and becomes extreme in the bronchitic or "asthmatic" attacks and in foggy weather. Cyanosis is common, and is to some extent a measure of the degree of emphysema. The patient may walk about with a more extreme degree of cyanosis than in any other condition except congenital

heart disease. Clubbing of the fingers of moderate degree is common. Cough is usually due to the associated bronchitis, and is worse in the winter and in foggy weather. It is frequent, noisy and often hacking and paroxysmal. Expectoration is also the result of the bronchial catarrh, and varies from a few grey mucoid pellets to copious muco-pus.

The chest is enlarged, particularly in the antero-posterior diameter, the upper thoracic spine is rounded and kyphotic, the sternum protrudes forward, and the angle of Louis (angulus Ludovici) is prominent, the general effect being the so-called barrel-shaped chest. The ribs run forward less obliquely and the intercostal spaces are wider than normal, the chest being as a whole in the inspiratory position. The respiratory movements are much restricted, the patient elevating the rigid thorax with little expansion on taking a deep breath, so that the inspiratory increase at the level of the nipples may be only half to 1 inch, instead of the normal $2\frac{1}{2}$ to 3 for an adult. There is often filling and even bulging of the supra-clavicular hollow, while the neck appears short, the sternomastoids stand out, and the jugular veins are full. A zone of dilated venules, the "emphysematous girdle," is often visible along the line of the costal attachment of the diaphragm, but is not pathognomonic. The cardiac impulse is not visible as a rule, and may only be felt with difficulty, but epigastric pulsation is usually apparent. Vocal fremitus is diminished, and the percussion note is hyper-resonant. The superficial cardiac dullness is greatly diminished or even absent, and the lower limit of pulmonary resonance may extend to the costal margin, back and front, the hepatic dullness being encroached on.

It is said that in bullous emphysema the breath-sounds are harsh over the outer part of the upper lobes in front, and weak at the bases. In general emphysema the breath-sounds are weak everywhere, inspiration is short, and expiration is greatly prolonged. A loud rumbling, from contraction of the thoracic muscles, may entirely obscure the breath-sounds. A few fine bubbling râles may be heard at the bases or at the sternal margins. If bronchitis is present, scattered rhonchi may be audible. Vocal resonance is generally slightly diminished. The heart-sounds are weak and distant, and in late stages a tricuspid systolic murmur may develop. The "vital capacity" of the lungs, measured by a spirometer, is often reduced even to one-half; for example, to 1800 c.c., instead of the normal 3600 c.c. Examination by the X-Rays shows increased extent, and undue translucency of the lung tissue. The liver is sometimes palpable, possibly from downward displacement by the bulky lung, but more often from enlargement due to passive hyperæmia. The spleen may also be depressed and enlarged.

Complications.—Bronchitis is the commonest, and often constitutes a vicious circle. Asthmatic attacks, so-called "bronchial asthma," are common in later stages; on the other hand, spasmodic asthma may be the cause of the emphysema. Pneumothorax and interstitial emphysema may occur from rupture of the bullæ, although these accidents are surprisingly rare. Pulmonary tuberculosis is an occasional complication of emphysema, which, contrary to popular opinion, is not antagonistic to it, although it may mask and obscure the early stages. Right-sided cardiac failure, with its train of consecutive changes, is a late and often terminal complication.

Course.—Emphysema is progressive, unless the cause is removed or the effects of the disease are mitigated by residence in a warm, dry climate,

especially in the winter. Conversely, residence in unsuitable districts, persistence in detrimental employment, and repeated attacks of bronchitis accelerate its course.

Diagnosis.—This is never difficult in advanced cases. The slighter degrees may be more difficult, and the diagnosis is then largely a matter of inference from the association of chronic cough and dyspnoea, with physical signs of hyper-resonance and prolonged expiration.

Confusion may occasionally arise in regard to pneumothorax, thoracic aneurysm and pulmonary tuberculosis. Careful record of the symptoms and signs and the investigation of the sputum generally suffice to distinguish these conditions. In doubtful cases the X-Rays may assist.

Prognosis.—This depends upon the degree of emphysema and the circumstances of the patient. If progressive, it exerts an increasingly crippling effect, and it certainly shortens life under urban conditions. A "vital capacity" of less than 50 per cent. of the normal is of serious import. The advent of severe bronchitis or of cardiac complications may affect the prognosis gravely.

Treatment.—Emphysema may be arrested but cannot be cured. Attention must be directed to prevention of the causes of chronic cough and increased intra-alveolar tension. In any person with hereditary tendency to emphysema or to winter cough, the questions of occupation and place of residence should be carefully considered. When the disease is established, the patient, if in a position to afford it, should spend the winter in a warm, dry climate, either abroad or at the south-west coast of England.

Various attempts have been made to increase the respiratory ventilation of the lungs, *e.g.* by compression of the chest during expiration, by expiring into rarefied air, or by breathing compressed air. Of these the compressed air bath seems to have given the best results. The patient enters a special iron chamber fitted with a window, and the air pressure is raised during the course of half an hour to $1\frac{1}{2}$ atmospheres. He remains at this pressure for an hour, and is then decompressed to normal during the next half-hour. These baths may be given every other day and gradually increased in duration and frequency. This treatment is often efficacious in cases of emphysema associated with bronchial spasm or with bronchitis. It is possible that the increased pressure overcomes the obstruction caused by catarrhal inflammation or by spasm of the finer bronchi, and allows the alveolar air, pent up under pressure, to escape. Cases with marked arterial disease or with much rigidity of the chest-wall are unsuitable for this form of treatment.

The diet should be simple and easily digestible, especially in the later stages. If there is spasmodic dyspnoea or asthma, no late meal should be permitted. Cod-liver oil in the winter seems to help some patients. Clothing should be warm, but the excess of under-garments, often worn in fear of chill, is harmful.

In other respects treatment is largely symptomatic. In acute bronchitis attacks the measures to be adopted are in no way different from those in bronchitis uncomplicated by emphysema. In the more chronic bronchitis so commonly present in the winter, iodides with alkalis and balsamic expectorants seem beneficial. Terebene (M x) in emulsion or in capsule has been recommended. Counter-irritation to the chest by liniments, such as the

lin, terebinthinæ aceticum, is often grateful to the patient, when cough is troublesome. When asthma or paroxysmal dyspnœa occurs, antispasmodic drugs and measures similar to those used in spasmodic asthma may be employed. When cardiac failure supervenes, the appropriate treatment must be vigorously applied. If there is marked cyanosis and venous engorgement, venesection, leeching, purgative and diuretic drugs may be employed, and digitalis and other cardiac tonics administered.

2. SMALL-LUNGED EMPHYSEMA (ATROPHIC OR SENILE EMPHYSEMA) *

Ætiology.—This condition occurs in old age and forms part of the general atrophy of the tissues.

Pathology.—The alveolar walls become thinned and disappear, so that adjacent alveoli coalesce. The condition is primarily atrophic, and therefore differs from true emphysema, although the result is to produce a diminished area for aeration. Post mortem the lungs are small and do not bulge or obscure the pericardium. They are often deeply pigmented, and are more spongy than normal, but although bullæ occur they are small. On section the lung tissue is bloodless and friable. The bronchi may be slightly dilated and show catarrhal changes.

Symptoms.—These are slight and are masked by the enfeeblement due to the general atrophy and debility. There is shortness of breath only on exertion, or on exacerbation of the chronic bronchitis which is frequently present. The chest is small, flat and thinly covered, the movements are poor and there is elevation of the chest as a whole, with poor expansion. There is little cyanosis, and no clubbing. The vocal fremitus is unaltered or slightly diminished. The percussion note is hyper-resonant, but there is no encroachment on the cardiac and hepatic areas of dullness. Breath-sounds are weak, and there is but little prolongation of expiration. Rhonchi and râles may be heard, especially if bronchitis is present, or if the heart is failing.

Diagnosis.—The condition is generally so obvious that no difficulty arises.

Treatment.—This is chiefly a matter of careful regimen and diet, with treatment of coexisting bronchitis or cardiac failure.

3. COMPENSATORY EMPHYSEMA (LOCALISED OR SECONDARY EMPHYSEMA)

Ætiology.—Localised emphysema is a sequel to some process inducing collapse, contraction or destruction of areas of lung tissue. It may be lobular in distribution in bronchitis, broncho-pneumonia, tuberculosis and diphtheria. It may affect one or more lobes, or the whole of one lung, especially in cases of fibrosis following tuberculosis, pneumonia, chronic pleural effusion and empyema.

Pathology.—It is generally conceded that the inspiratory theory of Laennec and Gairdner satisfactorily explains the genesis of this condition. When shrinkage of an area of lung occurs, the chest wall may fall in, if there is pleural adhesion, but otherwise inspiration tends to expand the normal parts of the lungs so as to contain the normal intake of air or the major part of it, owing to the difference it induces between the intrapulmonary and intra-

pleural pressures. None the less, it must be admitted that the expiratory strain of cough may assist in its production.

Although it may be compensatory and physiological at its inception, it is doubtful whether a true hypertrophy takes place after adolescence. In any case it soon leads to atrophy of the alveolar walls, as in true emphysema, and thus becomes pathological and harmful. Post mortem the condition may be found in an upper lobe around contracted scarred lung tissue, or in a lower lobe when the upper lobe is contracted or disorganised. In cases where one lung is fibroid and contracted, compensatory emphysema may be found throughout the sound lung. The enlargements and contractions of the lung may produce some striking displacements, the lower lobe extending upwards nearly to the clavicle, or the anterior margin of the sound lung crossing the mid line. The general appearances are closely similar to those of ordinary emphysema, except that bullæ do not occur, at any rate until the process is advanced and definitely pathological.

Symptoms.—This condition does not produce symptoms that can be differentiated from those of the primary disease. When it affects a lobe or the whole of one lung, there is hyper-resonance over the area involved, which often contrasts strikingly with the dullness due to the primary lesion. The hyper-resonance may extend across the sternum and even for an inch or more beyond it. The heart is displaced towards the side where fibrosis is in progress. Vocal fremitus and vocal resonance are little altered, but may be increased at first and subsequently diminished. In the early stages, when there is alveolar dilatation without degenerative mural changes, the breath-sounds are exaggerated, harsh or puerile, but when such processes develop, they become weak and there are indications of dyspnoea and cyanosis on exertion.

Diagnosis.—This is easy, owing to the difference between the diseased and "compensatory" areas, and to the indications of contraction and displacement.

Treatment.—No special treatment apart from that of the primary condition is required.

4. ACUTE VESICULAR EMPHYSEMA

Although custom has included this condition with emphysema, it is in reality only a temporary acute distension of the alveoli resulting from any condition causing widespread obstruction of the smaller bronchi. It is sometimes observed after death in cases of acute bronchitis, whooping-cough or asphyxia, and its existence may be inferred in severe asthma. Post mortem the lungs are bulky and the alveoli distended.

The symptoms are dependent upon the primary condition, although dyspnoea is invariably present. The chest is found to be fully expanded, the vocal fremitus is diminished, the percussion note is hyper-resonant, and the breath-sounds vary with the condition inducing it.

5. ACUTE INTERSTITIAL EMPHYSEMA

In acute interstitial emphysema air is present in the stroma of the lungs and in the subpleural connective tissues. It may follow external trauma, such as fractured ribs, or wounds penetrating the lungs. The alveoli may rupture with violent expiratory efforts, as occur in whooping-cough or

influenzal broncho-pneumonia. It may occur in diphthéria. The air sometimes tracks along the pulmonary roots to the mediastinum, and appearing in the neck or on the chest-wall gives rise to surgical emphysema.

Post mortem, subpleural bullæ may be seen containing air, and on section of the lung minute air vesicles may be found in the inter-alveolar connective tissue. A diagnosis cannot be made unless the physical signs of surgical emphysema are present. The air is usually completely absorbed, and a perfect recovery takes place. No special treatment is required beyond keeping the patient at rest, and giving sedative drugs to allay cough.

ABSCESS OF THE LUNG

Definition.—Abscess of the lung includes any circumscribed collection of pus formed in the lung tissue, but softened tuberculous areas and bronchiectatic accumulations are usually excluded.

Ætiology.—*Predisposing causes.*—These include any diseases producing general cachexia or malnutrition, notably diabetes and chronic alcoholism, also any conditions leading to diminished resistance locally in the lung, such as injury, disease or exposure.

Exciting causes.—These are pyogenic organisms, which reach the lung by inhalation, by extension from adjacent suppurative processes, or by the blood stream, either directly or in septic emboli. The common organisms found are streptococci, staphylococci, the pneumococcus, Friedländer's pneumo-bacillus, and the *Bacillus coli*—sometimes acting in conjunction with putrefactive bacteria. Spirochaetes, treponemata and anaerobic organisms are often present, especially after rupture has occurred. Pulmonary abscess may form under the following conditions:

(1) After inhalation of foreign material into a bronchus. This may be a foreign body, or may occur in association with septic conditions in the nose, nasopharynx and larynx, or during and after operations in these regions. These are referred to as inhalation abscesses. (2) As a result of lobar or lobular pneumonia, especially after the deglutition and aspiration varieties of the latter. Such abscesses are sometimes called meta-pneumonic. (3) Embolic causes—in pyæmia, or following on septic pulmonary emboli due to right-sided septic endocarditis, or derived from distant septic processes, such as otitis media, and infective thrombo-phlebitis. Amœbic abscess occurs occasionally after dysentery, and pulmonary abscess may be found as a rare complication of enteric fever. Some post-operative cases are regarded as due to embolism and not to inhalation. (4) From infection of the lung tissue due to spread from adjacent disease. This may occur in bronchiectasis, in ulcerating new growths of the lung, bronchi, œsophagus or mediastinal glands, in caries of the vertebræ or ribs, and in suppurating mediastinal glands. Rupture of an empyema, of a subphrenic abscess, of a liver abscess, or of infected hydatid cysts of the lung or liver may also lead to pulmonary suppuration. Ten per cent. of cases of abscess are due to new growths. (5) As a sequel of perforating chest wounds, or of fractured ribs piercing the lung.

Pathology.—Abscess of the lung is generally single and basic when consequent on pneumonia, whereas embolic abscesses are often small and multiple and may be found in any part of the lung. Abscesses due to extension from

adjacent disease are generally solitary, and are often large and irregular. The walls of acute abscesses are generally formed of congested and œdematous lung tissue, or of a zone of unresolved pneumonia. Since acute abscesses commonly rupture quickly into a bronchus, a fibrous capsule is unusual, but in chronic abscess there is often considerable fibroid change in the neighbouring lung tissue. The pleura may become involved over superficial abscesses, leading to empyema, or to pyo-pneumothorax if rupture follows.

Symptoms.—Abscess may develop insidiously, with comparatively slight symptoms. More commonly they are an intensification of those due to the primary or antecedent condition. The patient often appears seriously ill, the fever becomes of septic type, remittent or intermittent in character, and of a high range. Rigors and sweating are common. The pulmonary symptoms at first may be only slight cough with scanty muco-purulent expectoration. Dyspnoea may be present and pain of acute character develops if the pleura is involved. Hæmoptysis occurs in 70 per cent. of cases of abscess. A considerable leucocytosis, up to 20,000 or 30,000 may be found, and occasionally the breath may be offensive, even before rupture into a bronchus occurs, leading to the sudden expectoration of a large quantity of pus. The pus is sometimes unpleasant or offensive-smelling, but has not the extreme fœtor of gangrene. Microscopical investigation will demonstrate the presence of pulmonary debris, especially elastic tissue, together with pus cells and micro-organisms. After the expectoration of the pus, the temperature usually falls and the general condition of the patient is much improved, though cough and expectoration persist. In chronic cases after rupture the temperature may become irregular and periodic, a few days of normal temperature being followed by a period of fever and later by increased expectoration. The physical signs in a deep-seated or small abscess are often inconspicuous, and comprise slight dullness over a small area, weak breath-sounds and possibly a few râles in the surrounding infiltrated or œdematous lung tissue. With a large or a superficial abscess, the signs before rupture may be those of consolidated or collapsed lung. After evacuation occurs, the characteristic signs of excavation develop at once. In multiple embolic abscesses the signs are usually those of disseminated broncho-pneumonia.

Complications and Sequelæ.—The commonest complication is dry pleurisy. This may progress to empyema, or to pyo-pneumothorax, if rupture into the pleura occurs. In some cases mediastinitis or pericarditis may develop. Gangrene is described, but is a rare sequel. Metastatic abscesses may be produced in other parts of the body, especially in the brain, and meningitis is a rare and serious complication. The most important sequelæ are fibrosis of the lung, with bronchiectasis, pleural adhesion, and rarely indurative mediastinitis.

Diagnosis.—This is difficult before rupture, but abscess may be suspected from the gravity of the symptoms in relation to the history and signs, especially if leucocytosis and fœtor of the breath are present. X-Ray examination may be helpful, by demonstrating a localised shadow before rupture, and excavation afterwards, and also by establishing the situation of the abscess. A fluid level can often be seen in films taken in the erect position. The sudden expectoration of pus, followed by retrogression of symptoms and signs of excavation is very suggestive of abscess. After rupture has occurred the differential diagnosis has to be considered from :

1. *Interlobar empyema*.—This may be very difficult* or even impossible. In this condition the signs are generally most marked in the region of an interlobar septum, there may be some cardiac displacement, and the sputum, though purulent, does not contain elastic tissue.

2. *Bronchiectasis*.—The history, the characteristic cough and sputum, and the variation of the physical signs with the state of the cavity usually suffice to distinguish this condition. An X-Ray examination after lipiodol will distinguish in doubtful cases, since lipiodol does not as a rule enter the abscess cavity and the appearances in bronchiectasis are characteristic.

3. *Gangrene of the lung*.—The distinction is not always easy in acute abscess, since the two processes are closely related. The extreme gravity of the patient's general condition and the horrible foetor of the breath and sputum are the most characteristic features of gangrene.

4. *Tuberculous excavation*.—The history, the distribution of the signs, and the characters of the sputum, including the presence of tubercle bacilli, are the distinguishing indications.

5. *Purulent bronchitis*.—The history, the widespread physical signs, and the absence of elastic tissue from the sputum usually serve to establish the diagnosis, and lipiodol investigations may be helpful.

In multiple or pyæmic abscesses, it is often impossible to recognise the condition, though it may be suspected from the severity of the symptoms and signs. In any doubtful case an X-Ray examination should be carried out, if the condition of the patient permits. The possibility of malignant growth as a cause of abscess should be borne in mind and when necessary, bronchoscopy as well as lipiodol investigation carried out. Exploratory puncture as a means of diagnosis is dangerous and should be avoided.

Prognosis.—The prognosis, though grave in all cases, is better than might be anticipated. Many of those in which rupture into a bronchus occurs recover. The chance of recovery is greatly increased by operation. Death is inevitable in the pyæmic cases.

Treatment.—(1) *Medical*.—In acute abscesses medical measures should be employed, since in a considerable proportion of cases, recovery may occur after rupture, especially when the abscess is in the upper lobe. Before rupture the treatment should be similar to that for acute pneumonia. After rupture, evacuation should be promoted by "tipping," or postural drainage. Expectorant drugs and antiseptics, such as creosote, should be employed. Antiseptic inhalations may also be used on a Burney-Yeo mask, as for bronchiectasis, or creosote vapour baths may be given. In like manner intratracheal injections of menthol, guaiacol and olive oil have been employed with benefit. In cases with spirochaetes, treponemata and anaerobic organisms in the sputum, intravenous injections of salvarsan or neo-arsphenamine may be administered with benefit. (2) *Surgical*.—If spontaneous rupture does not occur after the abscess has become localised and encapsulated, operation is indicated in order to prevent the walls becoming thick. Repeated bronchoscopic aspiration is now being increasingly employed after rupture, and frequently gives satisfactory results. If after rupture, there is not satisfactory progress towards cure within 6 weeks, clinically and radiologically, surgical treatment should be invoked. Thoracotomy and open drainage is usually the operation of choice. This is now usually carried out in two stages: (a) a preliminary exposure of the pleura by rib resection and packing with

gauze, to ensure adhesion of the pleura; (b) some days later the abscess is opened along the course of an exploring needle. Artificial pneumothorax has been recommended, especially in deep or centrally placed abscesses. There is a risk of rupture into the pleura, more particularly when re-expansion of the lung is permitted. For this reason, this form of treatment is rarely advisable. Phrenic evulsion may aid in the evacuation of a chronic abscess, either alone or after thoracotomy. Pneumolysis, lobectomy, and thoracoplasty are also used in the treatment of chronic abscess.

GANGRENE OF THE LUNG

In this condition localised or diffuse areas of lung tissue undergo putrefactive necrosis.

Ætiology.—*Predisposing causes.*—These include old age, over-indulgence in alcohol, general debility, diabetes and insanity. In certain rare cases, especially after broncho-pneumonia complicating measles, gangrene of the lung is met with in children.

Exciting causes and associated conditions.—These are, in the main, identical with those of pulmonary abscess (see p. 1155). In addition, the pressure of aneurysm or of new-growth on branches of the pulmonary artery may lead to gangrene. The causal organisms are also very similar to those found in abscess of the lungs, and include staphylococci, streptococci, sarcinæ, the *Micrococcus tetragenus*, the *Bacillus coli communis*, the *B. pyocyaneus*, the *B. fusiformis* with its associated spirochæte, and various anaerobes. In some instances acid-fast bacilli, classed as streptothricæ, occur. Some of these organisms yield putrefactive products, with the liberation of phenol, indole and skatole compounds in the lung.

Pathology.—It is not quite clear what are the factors determining whether abscess or gangrene occurs in an infected area of lung. Doubtless the general resistance of the body, the degree of local vascular disturbance, and the virulence of the infecting organisms all play their part. Laennec first described the two varieties of gangrene, the circumscribed and the spreading or diffuse. Around the former there are indications of a line of demarcation, formed by congested lung tissue, which may present the appearance of red hepatisation. The surrounding lung tissue is invariably somewhat œdematous. The gangrenous area is soft and pulpy, and its colour varies from reddish-brown to greenish-black. As the necrosis advances, putrefactive liquefaction occurs, with the formation of a horribly reeking fluid, containing shreds and masses of necrotic lung tissue. When this is discharged, excavation results, and isolated vessels may be seen running across the resulting cavity, the walls of which are rough and covered with foetid pus. The diffuse variety of gangrene is less common; there is no attempt at a zone of demarcation, and the whole of a lobe or of one lung may be affected. In both forms, the overlying pleura is intensely inflamed, and empyema or pyo-pneumothorax may be produced.

Symptoms.—These are similar to those occurring in abscess of the lung, but are more acute. The patient is desperately ill, rigors are more common and sweating is more profuse. The breath has a peculiar fœtor, which, on account of the presence of the skatole group of putrefactive products in the

gangrenous lung, has an almost fæcal odour. The sputum is intensely offensive, and on standing separates into three layers, similar to those of the expectoration in cases of bronchiectasis. Elastic tissues are usually present, but it may undergo rapid disintegration. Hæmoptysis is not infrequent and may prove fatal. In rare cases gangrene is not accompanied by foetid expectoration, especially when developing in the insane, in young children, and in diabetics, or after pulmonary embolism. The physical signs closely resemble those present in cases of pulmonary abscess, and are those of consolidation before liquefaction occurs, and of excavation afterwards. The signs of the antecedent condition such as bronchiectasis, aneurysm, or malignant disease may also be present.

Complications and Sequelæ.—These are similar to those met with in pulmonary abscess, but owing to the rapid course and greater fatality of gangrene, they are not so common. Cerebral abscess may occur.

Course.—The course is usually rapid, unless the disease is small and circumscribed. In rare cases of localised gangrene of small extent, absorption and subsequent fibrosis occur.

Diagnosis.—The differential diagnosis is as for pulmonary abscess, the distinguishing features being the extremely critical condition of the patient and the revolting factor of the breath and expectoration. X-Ray examination may give great assistance if the patient's condition permits it to be made.

Prognosis.—This is invariably extremely grave, though a few cases of localised gangrene recover spontaneously. The prognosis is improved by early operation in suitable cases. The outlook is said to be worse if the condition is apical, and diffuse gangrene is invariably fatal.

Treatment.—Operation is indicated when the general condition of the patient permits, if the gangrenous area can be localised by physical signs or X-Ray examination. Exploratory puncture should not be carried out. The other operative procedures are similar to those for abscess of the lung. Operation is contra-indicated in cases of diffuse gangrene. The medical treatment is in all respects similar to that for pulmonary abscess. Injections of neocarsphenamine, in doses of 0·3 gramme, have given good results, especially in cases due to fuso-spirochætosis.

PULMONARY FIBROSIS

Synonyms.—Fibroid Disease of the Lung; Chronic Interstitial Pneumonia; Cirrhosis of the Lung.

Definition.—Pulmonary fibrosis is a late sequel of many acute and chronic inflammatory or irritative processes affecting the bronchi, lungs and pleuræ. It is therefore rather of pathological than of clinical interest, and in no sense constitutes a separate disease, although the end-results are remarkably similar in different forms. It is described here partly in deference to tradition, and partly to point out the methods of diagnosis between the various causes producing such strikingly similar effects.

Ætiology.—(1) The commonest cause is pulmonary tuberculosis, particularly the fibroid and fibro-caseous varieties. (2) The group of pneumoconioses contributes a considerable number of cases, and possibly some varieties of gas poisoning may induce fibroid changes. (3) Broncho-

pneumonic processes, particularly the forms associated with measles and whooping-cough, may be followed by widespread fibrosis, especially in children. (4) Although fibroid induration is commonly described as a sequel of lobar pneumonia, this disease is one of the rarer causes. (5) Localised fibrosis may occur around any circumscribed pulmonary or bronchial lesion, such as that produced by syphilis, leprosy, glanders or streptotrichosis. Similarly it occurs about infarcts, pulmonary abscesses and parasitic cysts. (6) Chronic venous congestion, if prolonged, leads to fibroid change, which is referred to as "brown induration." This is usually of moderate degree and does not affect the clinical manifestations. (7) Chronic pleural affections, particularly those leading to adhesions or causing pulmonary collapse, may induce fibroid changes within the lung, and these forms are described as "pleurogenous cirrhosis." (8) Any condition causing obstruction of a bronchus and leading either to collapse or to bronchiectasis may, if long continued, cause fibrosis of the corresponding lung area. Among such may be mentioned inhaled foreign body, new-growth, cicatricial contraction and thoracic aneurysm.

Pathology.—The fibroid overgrowth may be—(1) Massive or lobar; (2) localised or insular; (3) peribronchial; and (4) reticular.

Any part of the connective tissue framework of the lungs and bronchi may contribute to the fibrosis. In the massive form, which generally affects the whole or the major part of a lobe or even of one lung, the appearances in cases due to tuberculosis differ from those due to other causes. In the tuberculous variety the primary distribution is apical, and evidence of other tuberculous processes may be apparent in the form of large or small dried-up cavities, inspissated caseous material or calcareous masses enclosed in fibrous strands. In non-tuberculous processes, the early localisation is commonly basic, and although the primary cause may be obvious in the form of bronchial obstruction or some pleural condition, this is not always the case. On the other hand, non-tuberculous processes may involve the upper lobe primarily and fibroid tuberculosis may fall with special stress upon the lower lobe. In both forms of fibrosis, bronchiectasis may result, although this is more common in the non-tuberculous cases. Apart from the special tuberculous lesions, the end results are very similar in both forms. The affected area of the lung is shrunken and often devoid of air except for that in the bronchi and in the cavities. It is dark in colour, very firm and hard. On section it presents a mottled appearance owing to the strands of blue-grey fibrous tissue traversing it, contrasting with the pigmented, condensed, airless lung tissue. The fibroid area may be honeycombed by cavities or may present one large excavation, due either to tuberculous cavitation or to bronchiectatic dilatation. There is nearly always thickening and adhesion of the pleura. The contraction of the abnormal fibrous tissue leads to marked displacement of the heart and mediastinum.

The localised form is commonly due to healed tuberculous processes at an apex. There may be simple puckering with or without pleural thickening and adhesion, or a dense mass enclosing dried-up caseous matter or calcareous spicules. In bronchitic or broncho-pneumonic processes a patchy fibrosis may occur, described as insular fibrosis by Fowler.

Peribronchial fibrosis is common and figures largely in X-Ray reports on pulmonary cases. It is generally assumed that this is a sequel of tuber-

culous lesions acquired in early life. Although this is probably correct, it has not been incontrovertibly established.

Reticular fibrosis is a rare condition in which the fibrous tissue in the interlobular septa seems to become increased as well as that around the bronchi. It is at present only of pathological interest.

Symptoms.—The symptoms of pulmonary fibrosis are, in the main, expectoration and dyspnoea together with those of the primary affection. In the non-tuberculous cases, bronchiectasis is so frequently associated that the symptoms and signs found are practically those of this condition. Even in tuberculous cases, some degree of bronchial dilatation is the rule, although the sputum is rarely offensive. The cough is generally periodic and associated with change of posture. The expectoration is abundant, and if bronchiectasis is present, it has the usual characteristic features. The dyspnoea is proportional to the extent of lung involved. It may be extreme in the later stages, when the heart becomes embarrassed and begins to fail. Fever is usually absent, except when complications occur.

The patients are generally spare, although nutrition may sometimes be well maintained until late. They may show signs of deficient aeration in duskiess, cyanosis and congested cheeks. Polycythæmia of some degree is the rule. Clubbing of the fingers is almost constant. Evidence of contraction is generally forthcoming in the flattening and retraction of the affected side, with the dropped shoulder and compensatory spinal curvature. Movement is greatly restricted, contrasting with the increased expansion of the other side. The cardiac impulse is sometimes much displaced, especially in left-sided cases, when it may be in the left posterior axillary line or even under the angle of the scapula. In right-sided cases, it is drawn to the right of the sternum, even sometimes under or outside the right nipple. Vocal fremitus is usually diminished and percussion gives dullness of varying degree over the fibroid area, while the unaffected parts may be hyper-resonant from "compensatory" emphysema. The diaphragm may be drawn up, and the liver or stomach correspondingly displaced. The breath-sounds are often weak or inaudible unless there is bronchiectasis or cavitation, when the characteristic signs of these conditions can be recognised. The vocal resonance is diminished if there is much pleural thickening, increased if cavities are present. Adventitious sounds may be entirely absent, and when present vary from rhonchi and bubbling râles to coarse metallic râles, according to the presence or absence of excavation. X-Ray examination gives useful confirmation, showing displacement, excavation and pleural thickening.

Course.—The course is invariably chronic, and may extend to years, even ten or twenty.

Diagnosis.—The diagnosis is usually easy. The evidence of contraction and of mediastinal displacement towards the affected side, especially if signs of cavitation are also present, is highly suggestive. In the absence of the latter some difficulty may arise in regard to chronic pleural effusion or empyema. In the earlier stages the contra-lateral displacement of the cardiac impulse should prevent any mistake, but where partial absorption has occurred, this may be very slight or absent. In such cases an exploratory puncture or an X-Ray examination may be helpful.

1162 DISEASES OF THE RESPIRATORY SYSTEM

When the diagnosis of pulmonary fibrosis has been made, the differentiation of the cause is an essential to prognosis and treatment. If the condition is apical, there is a presumption in favour of tuberculosis; if basilar, some other cause is more probable. Repeated examinations of the sputum should be made for tubercle bacilli, and if these prove negative, X-Ray examination may reveal some cause such as new-growth, aneurysm or even foreign body. In some cases a careful consideration of the history may afford a clue to the diagnosis.

Prognosis and Treatment.—These depend upon the primary condition, but in most cases the latter is mainly symptomatic.

PNEUMOKONIOSIS

Synonyms.—Pneumonokoniosis; Dust Disease of the Lung.

Definition.—Pneumokoniosis comprises all the pathological changes induced in the bronchi, lungs and pleuræ by the inhalation of dust particles.

Ætiology.—*Predisposing causes.*—Pneumokoniosis is one of the occupational diseases. It is practically limited to men, and usually develops between the ages of 25 and 40. Defective ventilation, bad hygienic conditions and alcoholism promote its incidence.

Exciting causes.—Various forms of dust, both inorganic and organic, serve to produce pneumokoniosis, and in general the harder and more gritty the particles, the more marked are the changes induced. Organic forms of dust lead especially to bronchitic changes, the inorganic forms to pulmonary fibrosis.

The following varieties are recognised :

1. *Anthracosis*, from coal dust (coal-miners' phthisis).
2. *Siderosis*, from the inhalation of fine metallic particles in tin, copper, lead and iron-miners, and in grinders of steel goods (grinders' rot).
3. *Silicosis* or *chalicosis*, met with in workers in quartz, gannister and slate quarries, also in potters (quartz-miners' phthisis, and potters' asthma). Gold-miners' phthisis, the most serious form of pneumokoniosis, and especially prevalent in the South African gold mines, is due to the fine dust caused by the rock drills.
4. *Byssinosis*, a rare variety, is met with in cotton workers, felt-hat makers, and the employees in shoddy mills.
5. *Asbestosis*.—A condition found occasionally in those working in the manufacture of asbestos articles.

Pathology.—The lungs of persons living under rural conditions are practically free from deposited pigment. A certain amount of carbon is invariably present in the lungs of town-dwellers, giving them a dark-grey mottled appearance, but producing no pulmonary fibrosis. In coal-miners this occurs to such an extent that the lungs are black (anthracosis), although even here little fibrosis occurs, except in miners of hard coal or anthracite. In siderosis and silicosis, fine sharp particles of metallic oxides or silica are deposited in the lung tissue. In asbestosis, curious irregular discoid structures of golden yellow colour and containing iron, now called "asbestosis bodies," are found in the lungs and in the sputum. There is also much fibrosis, and tuberculosis is liable to be a later development.

It is generally accepted that these particles are conveyed to the bronchi and alveoli by inhalation. It has been suggested by Calmette and others that they are swallowed and reach the lungs through the mesenteric and bronchial glands. It is admitted that particles can reach the lungs by this route under experimental conditions, but this factor is certainly of small importance in the genesis of pneumokoniosis. In normal breathing, most of the coarse particles are detained in the nose, and are discharged with the nasal mucus, whereas in mouth-breathers they readily gain access to the trachea and bronchi. Even then, the coarser particles may be discharged in the expectoration through the agency of the ciliated epithelium, but, owing to the catarrhal processes induced by the irritation of the inhaled dust, this epithelium may be desquamated and the absorption of the particles is promoted. As a further consequence of this initial bronchitis, the finer particles may reach the alveoli, and passing between the epithelial cells, gain access to the tissue spaces, or in some cases they may be taken up into special "dust cells." Later, particles of dust become deposited in the connective tissue, and chronic peribronchial and perialveolar fibrosis develops. The bronchial glands also become enlarged and pigmented by the deposition of similar particles conveyed by the lymphatics. Other changes more or less constantly present are emphysema, pleural adhesion and bronchiectasis.

The relationship to tuberculosis has been much debated. It is now established that pneumokoniosis is non-tuberculous in origin, and that it may remain so throughout its course. On the other hand, certain forms undoubtedly favour the development of tuberculosis. In England and Wales coal-miners suffer less from tuberculosis than do all other males. On the other hand, gold-miners are extremely liable to it. It would appear that the determining factor is the presence of particles of silica. Silicates, as in clay, do not induce tuberculosis. Workers in freestone develop this disease, limestone workers do not. Slate quarriers do not acquire tuberculosis very readily, while metalliferous miners working in quartzite very frequently suffer from it. Mavrogordato describes three types of silicosis. (1) Silicosis, the damage found being due to dust alone. It is non-progressive if exposure ceases. (2) Tuberculo-silicosis, in which most of the damage is due to dust and tuberculosis is secondary. (3) Silico-tuberculosis, in which the chief lesions are due to the tubercle bacillus and the silicosis is secondary or at any rate less marked. Haldane and Mavrogordato have demonstrated that particles of coal are absorbed by the "dust cells" whose movements are thereby stimulated, with the result that they appear in the black spit, which is therefore a healthy sign. The particles of silica are also absorbed by these "dust cells," but no stimulus to their movement is induced and they remain *in situ*.

Post mortem, the lungs are generally firm and pigmented, the colour varying with the cause, being black in anthracosis, reddish-brown in siderosis, and greyish-black in silicosis. The pleura is generally adherent, especially at the bases. On section the lungs are firm, and often gritty. Small hard nodules may be felt with the finger. Fibroid changes are especially marked in silicosis. The bronchi are inflamed and sometimes dilated. Some degree of emphysema is usually apparent. If tuberculous lesions are also present, these vary from fibroid areas to miliary nodules. Destructive processes resulting in cavitation may also be seen. Microscopically, the alveolar

walls are thickened, the connective tissue is everywhere found to be increased, the "dust cells" may be seen in the connective tissue or in the alveoli, and particles of pigment or silica are found widely deposited in the connective tissue cells.

Symptoms.—The onset is insidious, bronchial irritation and cough, especially in the morning, may be the first indications, but increasing shortness of breath and debility are frequently early symptoms. The expectoration, at first scanty and mucoid, becomes more abundant and may present characteristic features as in the "black spit" of anthracosis. Tinging of the sputum and later hæmoptysis occur, but these suggest the possibility of superadded tuberculosis. The patient may appear healthy and be but little troubled except by the shortness of breath, but later emaciation and an appearance of premature old age are not uncommon.

The physical signs are not characteristic; at first they are simply those of persistent bronchitis, then emphysematous changes may become apparent. Later, signs of fibrosis appear, very similar to those described in the preceding section. Even when tuberculosis develops the signs are often but little characteristic, and repeated sputum tests may be necessary to establish the diagnosis. Examination by X-Rays may be helpful; at first there is an increase in the reticulation and later nodulation, somewhat like that of miliary tuberculosis. At a still later stage, the nodules become larger, and there is increased fibrosis. The changes characteristic of tuberculosis may be super-added.

Complications and Sequelæ.—The most important complication is tuberculosis, which forms the terminal stage of many cases of silicosis. This may be suspected when fever, night sweats, hæmoptysis or emaciation develop. Bronchiectasis of considerable degree sometimes results as a consequence of the fibrosis, and leads to the symptoms and signs characteristic of that condition.

Course.—This is progressive, unless the sufferer is removed from the exciting causes. Anthracosis runs a very chronic course, siderosis somewhat less so, while gold miners only live a few years (5 to 6—Oliver) after the onset of the disease.

Diagnosis.—The diagnosis can usually be made from the history of shortness of breath, cough and expectoration, developing in a worker in a dusty occupation. In the early stages, cigarette-smoker's cough and bronchitis may give rise to difficulty. In the later stages, the possibility of a primary fibroid tuberculosis has to be considered.

Prognosis.—This is unfavourable except in anthracosis. If recognised early, and if the patient is taken from the dusty conditions, recovery may be anticipated. The development of tuberculosis affects the outlook very gravely.

Treatment.—*Prophylactic.*—Every means should be adopted to avoid the dusty conditions leading to the disease. Mines should be well ventilated, and respirators should be worn where practicable in dusty occupations. Factories and workshops should be provided with apparatus to draw away dust. Sprays or jets should be used with drills to moisten the dust produced.

Curative.—Directly the condition is diagnosed, the patient should be advised to change his occupation. Nutrition should be kept at a satisfactory level. Symptoms and associated conditions, such as bronchitis or tuberculosis, should be treated on general principles.

PULMONARY TUBERCULOSIS

Synonyms.—Phthisis ; Consumption ; Decline.

Pulmonary tuberculosis embraces all the abnormal conditions induced by infection of the lungs, pleuræ and bronchial glands with the tubercle bacillus.

Ætiology.—**PREDISPOSING CAUSES.**—**Age.**—The maximum age incidence is between the 15th and 45th years, although the disease may be encountered at any age. Senile tuberculosis is more common than is generally recognised.

Sex.—The disease is more frequent in males, but between the ages of 5 and 15 the female sex shows a preponderance.

Heredity.—Pulmonary tuberculosis certainly occurs with undue frequency in certain families. Since the direct transmission of the tubercle bacillus to the infant is extremely rare, two explanations seem possible—(1) Children born of tuberculous stock may inherit an increased susceptibility or diminished resistance, the tuberculous diathesis ; or (2) they may contract tuberculosis on account of their exposure to massive infection in early life.

Race.—Differences in racial susceptibility probably depend upon the degree of inherited resistance acquired by the race from infection of previous generations. Native races suffer severely when first exposed. In Europe the Irish are particularly susceptible, whereas the Jews are relatively immune.

Climate.—Tuberculosis occurs in all climates. The prevalence of strong rainy winds and defective subsoil drainage may tend to increase its incidence.

Occupation.—The highest mortality from tuberculosis occurs in England amongst the workers in dusty occupations, thus Cornish tin miners head the list. On the other hand, coal miners are notably free from the disease. Any conditions leading to overwork or to underfeeding increase the liability to tuberculosis.

Environment.—Overcrowding, defective sanitation, dampness, dirt, lack of sunlight and insufficient ventilation are most potent factors in the spread of the disease, causing both lowering of the resistance and increased facilities for direct infection.

Trauma.—Trauma, involving the chest-wall, may be followed by active pulmonary tuberculosis. This is probably because the injury leads to activity of previously arrested disease, rather than to fresh infection at a spot of lowered resistance.

Gassing.—In certain cases the inhalation of poison gases causes rapid activity and spread in latent disease, or it may possibly prepare the ground for reinfection, but it is not a factor of great ætiological importance.

The influence of other diseases and conditions.—The following diseases predispose to the development of pulmonary tuberculosis : measles, especially when complicated by broncho-pneumonia, whooping-cough, influenza, pneumokoniosis, alcoholism, diabetes, syphilis, congenital heart disease and insanity. Tuberculosis may manifest itself for the first time during prolonged lactation or after repeated pregnancies ; when previously existent it often remains quiescent during pregnancy, but it may spread rapidly after childbirth. Contrary to the usual belief, pulmonary tuber-

culosis not infrequently coexists with mitral stenosis. A partial antagonism between tuberculosis, asthma, emphysema and gout has been assumed. Cases apparently following pneumonia, pleurisy or bronchitis are usually tuberculous from the onset.

EXCITING CAUSES.—The causal organism is the *Bacillus tuberculosis*, discovered by Koch in 1882. It exists in four main forms, human, bovine, avian and reptilian; only the two former usually occur in man, but avian infection has been recorded. The human type is found in over 97 per cent. of pulmonary tuberculous lesions. In glandular tuberculosis up to the age of 5 years, over 80 per cent. of the bacilli isolated conform to the bovine variety. In tuberculosis of bones and joints up to the same age, 29 per cent. of the cases are of bovine origin.

The bacilli may gain access to the body by inhalation, by alimentary ingestion, through the tonsils, through the skin, or possibly, in rare instances, by hereditary transmission. It is probable that in the majority of cases of pulmonary tuberculosis in adults, the organisms are carried direct to the lungs in the inspired air, and Ghon showed that in children, who had died of tuberculosis of the lungs, a primary focus was present in the lungs in 92.4 per cent. As, however, extensive tuberculous lesions are frequently found in the bronchial glands in cases of pulmonary tuberculosis, it is believed by some that the glands are primarily affected, and that the bacilli pass from them to the lungs, either against the lymphatic flow or in the blood stream. Calmette and others have demonstrated that the bacilli may gain access to the bronchial glands from the alimentary tract through the lymphatic duct, or from the tonsils through the cervical and mediastinal glands. Cases have been recorded in which primary cutaneous infections have been followed later by active pulmonary tuberculosis. Direct transmission of the tubercle bacillus is believed to occur only when the mother is suffering from advanced tuberculosis, and even then is of great rarity.

The incubation period of tuberculosis is uncertain, owing to the difficulty in determining when infection takes place. It is now believed by many authorities that the majority of individuals are originally infected in infancy or early childhood, either from the ingestion of tuberculous milk, or by the inhalation of bacilli from dried sputum. Pulmonary tuberculosis is thus regarded as a late manifestation comparable with the tertiary stage of syphilis. On this hypothesis, active pulmonary disease in adult life may result either from reinfection or from the activation of a dormant lesion in the body. As the organisms found in early life are frequently of the bovine type, whereas in pulmonary tuberculosis they are almost invariably of the human variety, it is probable that reinfection is the more common, since mutation of type has not so far been proved.

Provided that the proper precautions are taken, the risk of infection from person to person is not great, and only exists in "open" cases of tuberculosis, *i.e.*, in cases with tubercle bacilli in the sputum. There is no increased incidence in workers in hospitals or sanatoria for consumptives, and the occurrence of conjugal disease can be as well explained by mating of those with hereditary diathesis, as by direct infection.

Pathology.—The earliest lesion in the lung is the formation of tubercles, whose structure is described in the general article on tuberculosis. They appear first near the apex. This may be due to the relative immobility of

this portion of the lung, possibly as the result of calcification of the first costal cartilage (Freund), but in some cases the bacilli may spread from the cervical to the supraclavicular glands and thence to the adjacent lung. In some cases the earliest lesion is found in the subclavicular region well below the apex. It may commence in a subacute manner. In such cases, an area of localised deposit may be seen on radiological examination—known as Assmann's focus (Reckecker's "*früh infiltrat*"). The initial deposit is usually in or around the small bronchioles of the third to fifth degree (Hirschfeld's bronchioles). The inflammatory swelling of the bronchioles obstructs their lumen, leading to collapse of the alveoli beyond and the formation of bronchopneumonic areas. At the same time peri-bronchiolar inflammation develops. In children there is, in the majority of cases, a primary lung focus (Ghon's focus), with secondary deposits in the bronchial glands.

SECONDARY CHANGES.—1. *Caseation.*—The tubercle is avascular, and owing to this, and possibly also to the action of tubercle toxins, coagulation necrosis and fatty degeneration frequently ensue. This combined process is known as caseation and results in the formation of structureless, cheesy mass. Further changes may now occur, either softening, with the development of a "cold abscess" filled with tuberculous "pus," or calcification, with the subsequent formation of gritty masses known as "pneumoliths."

2. *Cavitation.*—Cavities result from the liquefaction of caseous areas, and the expectoration of the resulting debris. They may be no larger than a pea, or may occupy the whole of one or more lobes. A recent cavity has an irregular outline, with rough, shaggy walls and a vascular line of demarcation. It is often traversed by trabeculae, formed by bronchi and vessels which may be partly or completely obliterated, while sometimes the trabeculae consist of condensed lung tissue which originally separated adjacent cavities. In chronic cases, the cavity is surrounded by fibrosed lung tissue forming a pseudo-capsule, and its interior becomes lined by a thin, smooth, false membrane. Small aneurysms may be found, arising either from vessels running in the walls or in the trabeculae of the cavity, the former being the more common. In some cases, where hæmoptysis has occurred, rupture of such an aneurysm is the cause.

3. *Fibrosis.*—Reactive changes in the lung stroma lead to the formation of fibrous tissue. This may occur early or after caseation has taken place.

In the majority of deaths from all causes, old tuberculous lesions are found post mortem near the apex of one lung. These consist of small nodules of arrested disease, with thickening and dimpling of the adjacent pleura.

DISSEMINATION IN THE LUNGS.—The disease may spread from the primary peri-bronchial deposit—(a) By direct infiltration; (b) By the peri-bronchial lymphatics and capillaries, leading to a racemose appearance or to peri-bronchial fibrosis; (c) By the subpleural and interstitial lymphatics, with localised miliary dissemination; (d) By inhalation into a bronchus of tuberculous material, which is then carried to other parts of the same or to the opposite lung—this not infrequently happens after hæmoptysis; (e) By the blood vessels, e.g. generalised miliary tuberculosis may result from erosion of a caseous tubercle into a vein.

The pathology of the clinically distinguishable forms of pulmonary tuberculosis will now be described.

1. **ACUTE MILIARY TUBERCULOSIS.**—A primary caseous focus may be discovered at the apex of one lung, in the bronchial glands, or at some distant spot in the body. Local erosion of a vein may be found, accounting for the dissemination of the disease. The lungs are usually studded with minute grey tubercles, the smaller ones requiring a hand lens for their recognition. In very acute cases death occurs before any secondary broncho-pneumonic changes take place. Miliary tuberculosis may develop as a terminal event in chronic fibro-caseous or fibroid tuberculosis. The tubercles are then found in large numbers around the old foci of disease, but to a less extent in the more remote portions of the lung.

2. **ACUTE CASEOUS TUBERCULOSIS.**—Large areas of consolidation form rapidly, which differ histologically from the common chronic tuberculous broncho-pneumonia in that the alveolar exudate is more definitely inflammatory and contains fibrin. In the rare lobar cases, the rapid caseation and the presence of tubercle bacilli show that the caseous pneumonia is a specific process. Firm yellowish patches, which may be confluent, are seen, usually scattered throughout both lungs. The affected areas are airless and sink in water. Softening is generally present in varying forms up to actual cavity formation, which may be extensive, involving even a whole lobe.

3. **FIBRO-CASEOUS TUBERCULOSIS.**—This is the commonest variety of the disease; the appearances of the lung vary with the relative preponderance of the caseous and fibrotic changes. The early lesions are miliary or broncho-pneumonic, but areas of caseation in varying stages are always present. The older lesions show considerable fibrosis, the strands of sclerotic tissue being pigmented and glistening. The earliest lesion is usually near the apex of the upper lobe at the back, more rarely a little lower and towards the front. The apex of the lower lobe is next affected, and the disease then spreads in the direction of the interlobar septum. The apex of the upper lobe of the opposite lung is next involved (Fowler's law of spread). Pleural adhesions are usually present over the oldest lesions, and in the interlobar fissures.

4. **FIBROID TUBERCULOSIS.**—Fibrosis may be localised around a small arrested lesion, or may spread throughout a lung in which caseation or excavation has occurred. One lobe or the whole lung is then contracted and firm. In the interstices of the fibrous tissue, which is usually pigmented, inspissated caseous material, calcareous patches, or cavities are seen. The shrinkage may lead to bronchiectasis, especially in the lower lobes. The overlying pleura is much thickened and adherent, and the mediastinum is drawn over towards the affected side. The opposite lung, or the sound portions of the fibrosed one, may show compensatory emphysema.

The bronchial glands.—The tracheo-bronchial glands are affected in all forms of pulmonary tuberculosis. They are enlarged, sometimes pigmented, and may present miliary, caseous, calcareous or fibroid changes, in some cases primary, in others secondary to the lesions in the lungs.

The pleura.—This, too is almost constantly affected. The commonest changes are an early dry pleurisy, and a later thickening with adhesions which may completely unite the visceral with the parietal layers. In acute disease or active spread, the pleura may be studded with miliary tubercles, leading to a large serous effusion.

The post-mortem appearances of the lesions situated in the other organs, found as complications of pulmonary tuberculosis, are described in the

respective sections dealing with them, and include tuberculous meningitis, peritonitis, enteritis and genito-urinary tuberculosis. There is usually atrophy of the skeletal muscles, sometimes lardaceous and fatty degeneration of the liver, and hypoplasia with fatty degeneration of the heart.

Symptoms.—The symptoms fall into three groups (Pottenger)—(1) pulmonary, such as catarrh, expectoration, hæmoptysis and pleurisy; (2) reflex, such as pain, cough and laryngeal irritability; (3) toxæmic, including malaise, tachycardia, pyrexia and loss of weight.

ONSET.—The mode of onset is very variable, but certain forms can be recognised.

(a) **Insidious.**—The early symptoms may be malaise, anæmia, amenorrhœa, cardiac irritability, progressive loss of weight, and slight rise of temperature, generally towards evening. Cough and expectoration often appear only when the signs in the chest are quite apparent. When there is intestinal stasis, the cutaneous pigmentation may suggest the diagnosis of Addison's disease.

(b) **Catarrhal.** A series of febrile "colds" may usher in the disease, and such a sequence is always suspicious.

(c) **Phthisis ab hæmoptoe.**—Hæmoptysis may first draw attention to the lungs. It may be slight, and is then due to early congestion around the focus of infection. If it is more marked, it indicates breakdown of an old arrested lesion, or may afford dramatic evidence of extensive disease which had not been recognised previously.

(d) **Laryngeal.**—Hoarseness or aphonia may be the first symptom, but laryngeal tuberculosis is usually secondary to pulmonary disease, although the latter may have been unsuspected.

(e) **Gastro-intestinal.**—Anorexia and flatulence often occur early. When they are accompanied by slight loss of weight and pyrexia, the possibility of pulmonary tuberculosis should be suspected.

(f) **Pleural.**—Dry pleurisy is a frequent manifestation of latent pulmonary tuberculosis. When a serous effusion develops, its tuberculous character can be determined by laboratory investigations. Pneumothorax, developing in a previously healthy individual, is a rare but serious clinical mode of onset.

(g) **Pneumonic.**—"Gallop" consumption often begins with pneumonic manifestations, especially in the young.

(h) **Traumatic.**—Pulmonary tuberculosis may follow injury or "gassing," as described under ætiology.

(i) **Neurasthenic.**—Neurasthenia may occur as a complication of tuberculosis; but in some cases an initial neurasthenia dominates the picture, and the pulmonary lesion is only detected on careful examination.

(j) **Malarial.**—Regular attacks of sweating and fever may occur, especially in those who are or who have been residing in malarial climates, suggesting malaria, but in reality due to tuberculosis.

(k) **Associated with other diseases.**—Tuberculosis may follow immediately on an attack of measles, influenza or whooping-cough, especially if complicated by broncho-pneumonia. In some cases it develops at a later period after the acute disease.

(l) **Senile.**—In old people an insidious onset is common. The disease may be of bronchitic type, and the signs are often masked by emphysema. There may be little or no rise of temperature.

THE CHIEF SYMPTOMS of pulmonary tuberculosis are—

Cough.—This varies considerably in different types of disease. It may be very slight or absent in generalised miliary tuberculosis, or in any form in the insane. It is sometimes dry, persistent and ineffective, especially in miliary extension in the lungs from an old focus of disease, in bronchial gland tuberculosis, or in pleurisy. When there is associated bronchitis or caseation, the cough is usually accompanied by expectoration, which, if very tenacious, may lead to retching or even to vomiting, particularly in the morning. In laryngeal tuberculosis the cough is husky and frequently painful.

Expectoration.—In early disease there is usually no sputum, and in some cases, more especially in the fibroid type, widespread lesions may be present with practically no expectoration. When caseation is in progress, or when there is secondary infection with bronchitis, the sputum may be abundant and amount to as much as 20 or more ounces in the 24 hours. It may be clear or mucoid, or thick tenacious muco-pus. If mucoid, it often contains small particles, the size of a pin's head or larger, of yellow caseous material. Nummular sputum may be met with in active caseous disease, especially with excavation. This consists of flat rounded masses of muco-pus, with a somewhat distant resemblance to coins. In tuberculosis the sputum is usually inoffensive, but may have the characteristic sickly odour which is also noticed to emanate from the patient himself (odor phthisicus). If bronchiectasis or gangrene occurs as a complication, the expectoration becomes typically malodorous. Pulmonary calculi or pneumoliths, composed chiefly of calcium carbonate or phosphate, are sometimes expectorated. They vary in size from a pin's head to a pea, are irregular in outline and sometimes branched, being derived generally from the walls of a cavity. Although the occurrence of these does not necessarily indicate fresh activity in the lungs, yet such a possibility should always be suspected, and a careful watch maintained on the temperature during the next few days. In some cases larger pneumoliths, as big as a cherry, may be coughed up, and these are frequently derived from caseous tracheo-bronchial glands. They may give rise to alarming symptoms at once, and be the forerunner of fresh activity in the lungs.

The albumin reaction.—The significance of albumin in the sputum has been investigated by Ridge and Treadgold. It is found in nearly all cases of active pulmonary tuberculosis, and in the absence of tubercle bacilli, three consecutive negative albumin tests are strong evidence against the presence of active disease. Albumin, however, also occurs in the sputum in other destructive lesions of the lungs.

Microscopical examination.—The presence of tubercle bacilli in the sputum is the most decisive test of the existence of this disease. The small yellowish caseous particles should be selected from the sputum, and appropriately stained. If no tubercle bacilli are found, samples from the whole sputum of the 24 hours, concentrated by the antiformin method, can be examined. The cells present are usually of the mononuclear type either mononuclear leucocytes or altered alveolar epithelial cells. The presence of elastic tissue indicates that destructive pulmonary lesions are in progress. Secondary infecting organisms may be demonstrated by cultural methods.

Dyspnœa.—Slight dyspnœa occurring early in the disease may be due to

diminished movement of the diaphragm on the affected side. In more advanced cases the degree of dyspnoea is proportional to the amount of lung tissue involved. In addition, cough and pyrexia play a part in its production. Complications such as pleurisy, pleural effusion, pneumothorax and cardiac failure increase the shortness of breath. It is rare to find orthopnoea even in acute and rapidly spreading disease. In arrested cases the dyspnoea is proportional to the extent of fibrosis.

Cyanosis.—This is not an early symptom of tuberculosis. It is dependent upon the amount of lung tissue involved, but is increased by the coexistence of emphysema or cardiac failure. The typical "hectic flush" of tuberculosis is a vasomotor effect caused by toxæmia.

Pain.—Not every sufferer from tuberculosis experiences pain, even in the acute stages of the disease. The commonest cause of pain is dry pleurisy. When the diaphragmatic layer of the pleura is affected, pain may be referred to the epigastrium or to the corresponding shoulder. In chronic fibroid phthisis there is frequently a dull, aching pain in the chest, which is more noticeable in damp weather. This is caused by the contraction of the condensing fibrous tissue. Cutaneous tenderness of the chest-wall is met with in some cases of advanced disease, and is probably due to a cachectic neuritis. A "cold abscess" forming along one of the ribs or costal cartilages is a rare cause of localised pain in the chest-wall. Cough may be painful, especially when paroxysmal or frequent, the pain being referred to the costal attachments of the diaphragm and upper abdominal muscles. The sudden occurrence of pneumothorax may cause such severe pain as to induce collapse; but when of more gradual onset no severe discomfort may be experienced. Tuberculous laryngitis may be the cause of very great suffering.

Night sweats.—Although not pathognomonic, night sweats occur more frequently in tuberculosis than in other diseases. They are met with in all stages of active lesions, and may be of great severity.

Loss of weight.—This is often an early symptom. It is most marked in acute disease and in the late stages of chronic fibro-caseous tuberculosis.

Fever.—Pyrexia is one of the most important indications of activity at any stage of pulmonary tuberculosis, although it does not follow that the disease is arrested when there is no fever. During treatment the temperature should be recorded at certain definite hours in the day. (a) On waking. The normal mouth temperature at 7 or 8 a.m. is 97° or 98° F. in the mouth, and 97°·2 to 99° F. in the rectum. This temperature should be taken in bed, before eating or drinking. (b) At 1 p.m., after the hour's recumbent rest. (c) At 6 p.m. (d) At 9 p.m., after retiring to bed. The maximum temperature is usually reached between 4 and 6 p.m., but may be delayed to 8 or 9 p.m. In most sanatoria the rectal temperature is taken, and a centigrade thermometer employed. The temperature is dependent upon the extent and the activity of the disease, and upon the amount of exercise taken.

(a) In acute miliary tuberculosis.—It may be continuous or remittent, and the "typhus inversus" is not uncommon, the morning temperature being higher than the evening. This is generally regarded as a sign of grave prognosis.

(b) In acute caseous tuberculosis the high temperature at the onset is continuous, and the record resembles a pneumonic chart. When caseation occurs it becomes hectic or intermittent, with a daily swing of 4° or 5° F.

1172 DISEASES OF THE RESPIRATORY SYSTEM

This is probably due to the action of tubercle toxins, and not to the presence of a secondary infection.

(c) In chronic fibro-caseous tuberculosis there is no characteristic temperature record. There may be only a very slight rise occurring at intervals of a few days. On the other hand, the patient may be afebrile while resting, but febrile when ambulant (Stage 2. Inman's classification). Further an afebrile ambulant patient may over-exert himself, and by excessive auto-inoculation develop a sharp rise of temperature which subsides in a few days with rest. The temperature chart is thus a guide to prognosis and to treatment, and if acute miliary tuberculosis or caseation occurs, a typical temperature variation ensues.

(d) In fibroid tuberculosis the temperature is usually normal, unless excessive auto-inoculation results from exercise, or the disease advances. The occurrence of hæmoptysis may have a very definite effect upon the temperature. In some cases it is not followed by pyrexia, but if the inhaled blood leads to a hæmoptoic bronchitis, there may be a slight degree of fever lasting for a few days. When a definite and persistent pyrexia follows, it usually indicates activity around an old focus of disease, or fresh spread by inhalation of blood containing tubercle bacilli to a distant portion of the lung.

A premenstrual rise of temperature may occur; but as it is also met with in healthy women it is not pathognomonic.

Hæmoptysis.—Hæmoptysis occurs at some stage of pulmonary tuberculosis in about 50 per cent. of all cases. With early lesions the sputum is only streaked. This may result from the congestion of tuberculous bronchitis, or from a small area of collapse or broncho-pneumonia. In the pneumonic or broncho-pneumonic forms rusty sputum may be seen. Profuse hæmoptysis generally occurs in chronic disease; but it is occasionally met with in acute caseous forms. Recovery may take place after coughing up 2 or 3 pints, or death may ensue rapidly from suffocation before any considerable quantity of blood has been expectorated. After the cessation of bleeding the sputum may be coloured for several days. The source of profuse hæmoptysis is generally an aneurysm of a branch of the pulmonary artery lying in a cavity or in a fibroid lung, although occasionally ulceration without previous aneurysm formation may occur. In the majority of cases hæmoptysis begins while the patient is lying down or resting, so that exercise or work are not frequent exciting causes.

The patient notices a salt taste, feels a warm gush in the mouth, and then expectorates the blood. He is usually greatly alarmed, flushed and sweating, with rapidly beating heart. The blood at first is as a rule bright and frothy but some clots may be present; later it is mixed with muco-purulent expectoration, in the form of clots or streaks.

Circulatory system.—The heart may be small, but the right side often hypertrophies in chronic fibroid cases. Tachycardia may be due to nervousness, but when constant it generally indicates active disease or over-exertion on the part of the patient. The blood-pressure is usually low in the stages of activity, and a steady rise during treatment is a favourable sign. If tuberculosis is coexistent with other diseases, such as atheroma, which raise the blood-pressure, higher readings are naturally obtained.

The blood.—The red cells are usually normal in number, but there may be a slight anæmia. On the other hand, when there is much cyanosis, or

after sanatorium treatment, the red cells may be increased. The colour index is usually low. In the early stages the leucocytes may be slightly increased. A polymorpho-nuclear leucocytosis occurs in caseation and in early cavity formation, and at times with secondary infection of the lungs. A special differential count of the polymorpho-nuclear leucocytes themselves may be made by subdividing them into groups, according to the number of their nuclear lobes, as suggested by Arneth. An increase in number of immature cells with only one or two nuclear lobes constitutes a deviation to the left from the normal, and raises the Arneth index. This lævo-deviation is said to indicate toxæmia, and if it is not present, the disease will probably be chronic.

Alimentary system.—The tongue is usually clean and the appetite good even in cases with marked fever. When tuberculosis of the larynx is present, there is frequently severe dysphagia. Dyspepsia may be complained of, usually of a nervous type. Anorexia, flatulence, distension with nausea are the commonest symptoms, pain being rarely noticed. There may be marked intolerance of fat in the diet. The early hyperchlorhydria in tuberculosis, previously described, has not been confirmed by Mohler and Funk in America, using the fractional method of gastric analysis. Atonic dilatation of the stomach may occur in some cases towards the end of the disease. Constipation is common; on the one hand, diarrhœa may occur apart from intestinal ulceration or lardaceous disease.

Nervous system.—The classical "spes phthisica" is distinctly rare, but when present is very striking from its contrast with the realities of the disease. It is most commonly seen in acute caseous tuberculosis. More often the patient becomes emotional and self-centred, depression is common and hard to combat, and melancholia with delusions occasionally develops. Neurasthenia is frequent, and as mentioned above, may lead to errors in early diagnosis. Insomnia may be due to cough, pyrexia, night sweats or pain, especially in laryngitis. With marked cachexia, a definite peripheral neuritis may occur.

Genito-urinary system.—In the early stages there is often an increased sexual desire, and this may recur when arrest is taking place. This is probably in part due to the therapeutic régime, the rest, abundant food and lack of interesting occupation reacting upon the nervous system of young adults. In advanced disease, all sexual desire is lost. Menstruation often ceases early, and the patient may seek advice for amenorrhœa. Women remain fertile even in advanced disease. The urine is normal in the early stages, later a febrile albuminuria may occur, and casts or even sugar may be excreted without the occurrence of true nephritis or diabetes.

THE PHYSICAL SIGNS OF EARLY DISEASE.—The general appearance of the patient may be healthy, or may be that of malnutrition with the characteristics of the "habitus phthisicus," the hair being lank and lustreless, the skin white, thin, dry and shiny, and the thorax of the alar or phthinoïd type. Certain stigmata are described, which although useful, are not pathognomonic. The eyelashes may be long, dark and curling, the back hairy and the thoracic cutaneous venules dilated. When present around the upper thoracic vertebral spines, they are sometimes known as "the varicose zone of alarm." Deficient movement may be observed below one clavicle, at the point of one shoulder, or at the lower costal margin. The corresponding shoulder may be slightly drooping, with flattening above or

below the clavicle, and slight hollowing of the supra-spinous fossa with wasting of the trapezius muscle may be observed. Pottenger regards these shoulder signs, when not due to scoliosis or kypho-scoliosis, as reflex, and comparable with the fixation of a tuberculous joint and wasting of its adjacent muscles. In women it may be noticed that the breast on the affected side is smaller and hangs at a lower level, although a non-tuberculous mastitis is sometimes seen causing enlargement, especially in males.

Palpation confirms the diminished expansion, and reveals a slight increase of vocal fremitus over the affected area of the lung, usually at one apex. The normal increase in fremitus of the right apex over the left must be borne in mind, in order to prevent mistakes.

With light percussion slight dullness and a small increase in the sense of resistance can be detected. This is usually most apparent in the supra-spinous and upper interscapular regions. The extent of pulmonary resonance above the clavicle, known as "Krönig's isthmus," may be diminished by $\frac{1}{2}$ to 1 inch on the affected side.

Various types of breath-sounds may be heard over the affected portion of lung. They are—(a) weak inspiration, with expiration vesicular or inaudible; (b) cog-wheel inspiration, with expiration vesicular, prolonged or rarely jerky; (c) the "granular" breathing of Grancher, the breath-sounds being somewhat coarse and irregular, suggesting fine or distant râles, although none can be definitely detected; (d) harsh inspiration, with expiration vesicular or prolonged; (e) broncho-vesicular breathing; (f) definitely bronchial when early consolidation is in progress.

Often there are no adventitious sounds. Occasionally a few small rhonchi or fine crackling or bubbling râles may be heard with the first few deep breaths, or only with the inspiration immediately following coughing. If râles are constantly heard, it indicates that the lesion is already of some extent. Care must be taken to differentiate them from atelectatic râles, emphysematous râles audible along the sternal margin, and pleural friction or fascial creaks. There is usually a slight increase in the conduction of both the spoken and whispered voice, and the more definitely this extends away from the trachea in front, and from the vertebral spines behind, the more reliable is the sign as an indication of disease.

Mensuration is seldom practised in routine examination, but graphic records of the chest contour, which are of interest in following the progress of a case can be obtained by cyrtometry.

THE PHYSICAL SIGNS OF CONSOLIDATION.—Limitation of movement and flattening over the affected part of the lung, usually the apex, is now more noticeable.

The diminution of movement is confirmed on palpation, and vocal fremitus is found to be definitely increased.

The pulmonary resonance is diminished to definite dullness and the sense of resistance is correspondingly increased.

The breath-sounds are bronchial, or in acute caseous disease may even approximate to tubular.

Adventitious sounds may be absent, but usually fine or medium crackling râles are heard with inspiration, especially after coughing. When active softening is in progress the râles frequently become coarse and sticky.

The voice conduction is much increased, bronchophôny and whispering pectoriloquy being audible.

Mensuration may confirm the presence of flattening.

THE PHYSICAL SIGNS OF EXCAVATION.—Flattening of the chest-wall and diminished movement over the cavity are now more marked; if the cavity is apical there is in addition notable dropping of the shoulder, and wasting of the shoulder-girdle muscles.

The diminution of movement is confirmed by palpation. Vocal fremitus is generally increased owing to the surrounding consolidation, but if the cavity is full or there is much pleural thickening, it is diminished.

The percussion note is dull when the cavity is small or filled with secretion. A peculiar boxy or "cracked-pot" note, the "*bruit de pot fêlé*," is obtained over large superficial cavities, especially when communicating with an open bronchus. This is best heard on percussing with the mouth open, and Wintrich showed that the note may be altered in pitch over such cavities when percussing with the mouth open or closed, apart from the actual presence of the cracked-pot sound. Gerhardt's sign (alteration of note with the position of the body) is supposed to indicate a cavity of opal shape. It is rare, and of little value.

The breath-sounds are bronchial, broncho-cavernous, cavernous or amphoric, according to the size of the cavity, and to the amount of its contents. When it is full the breath-sounds may be distant, weak or even absent, and this is especially noticeable in basal bronchiectasis.

With a dry cavity there may be no adventitious sounds. Usually râles are audible; they may be medium or large, and bubbling or crackling in character. Over a large cavity a metallic tinkle and amphoric echo may be heard. With a very large cavity, extending through the whole of one lung, a typical *bruit d'airain* is at times obtainable. Voice conduction is increased, bronchophony and whispering pectoriloquy are present, and in some instances post-tussive suction is heard.

Mensuration affords a graphic representation of the flattening of the chest-wall.

THE PHYSICAL SIGNS OF FIBROSIS.—The chest is asymmetrical, the affected side being flattened and moving little, while compensatory scoliosis or kypho-scoliosis is often present. The cardiac impulse is seen to be displaced towards the affected lung and may be higher or lower than normal. It may be drawn over to the right axilla, or on the left side as far back as to the posterior axillary line, or even to the angle of the scapula. The intercostal spaces may be retracted, and dilated venules are sometimes seen over the front of the chest as the result of obstruction, caused by displacement of the mediastinum and traction on the deeper veins.

Diminution of movement is confirmed by palpation, and the cardiac impulse can be more accurately localised. Vocal fremitus may be increased or diminished; the former occurs when the lung is consolidated and the large bronchi patent, the latter when there is much pleural thickening.

The percussion note over fibroid lung is dull and the sense of resistance increased, unless cavities are present. The opposite lung may be hyper-resonant, and its resonance extend across the mid-sternal line. The cardiac dullness is often continuous with that of the fibroid lung, and its area can only be determined by the cardiac pulsation.

The breath-sounds are weak and distant, unless modified by the presence of a cavity.

Often there are no adventitious sounds, although fine or medium râles of a sticky or metallic nature may be heard. The voice conduction is usually diminished, and there is no pectoriloquy unless excavation has occurred, when bronchophony and pectoriloquy are audible.

It must be borne in mind that in actual disease, the lesions are not so clear-cut and well-defined. In a case of some duration different stages of disease can be found in the same individual, thus infiltration, consolidation with softening, excavation and fibrosis may be present in different lobes of the lungs, and so it is possible to determine the site of origin and path of spread of the disease.

Certain other signs are occasionally seen in pulmonary tuberculosis.

Myoidema is an undue irritability of the muscles to direct mechanical stimulation, revealing itself by a flickering fibrillary contraction on tapping with the finger, and may occur in tuberculosis at all stages. It is best seen over the pectoralis major on the affected side. It may be present quite early, but is not pathognomonic, as it may occur at any cachetic state.

Clubbing of the fingers is commonly seen in chronic cases, the nails are curved and present a parrot-beak appearance, the thumb, index and middle fingers being most affected. Drum-stick clubbing is only seen in fibroid lesions with bronchiectasis.

HILUM TUBERCULOSIS.—The existence of a special type of pulmonary tuberculosis commencing at the root of the lungs and extending thence in a fan-shaped manner along the bronchi has been postulated by some in recent years, chiefly on X-Ray evidence. While lesions in the middle zone of the lung are sometimes revealed by X-Ray examination, it is more than doubtful whether this condition merits recognition as a separate variety of the disease.

PULMONARY OSTEO-ARTHROPATHY.—In cases with bronchiectasis the joints also may be affected, swelling occurring especially in the wrist, ankles and knees, and rarely in the hips and shoulders. A serous effusion into the joints may be present. Pain is usually slight, but there is much deformity and functional impairment. X-Ray examination reveals productive periosteal changes, which may also affect the long bones and the spine.

RADIOGRAPHY OF THE CHEST.—If possible, the chest should be examined in every case with the fluorescent screen, and a photograph taken on a film or plate. Certain important points can only be determined by a screen examination. The chief of these are the respiratory movements of the diaphragm, lighting up of the apex of the lung with inspiration, and the cardiac pulsation. Unilateral restriction of diaphragmatic movement not infrequently occurs in early apical tuberculosis, but as it may be observed under other conditions, notably with pleural adhesions, it is not diagnostic. The film will show the extent of the disease and in some cases it may suggest the existence of activity; thus areas of consolidation, caseation or excavation can be demonstrated, and thickening of the pleura, pleural effusion and pneumothorax give their characteristic appearances.

The significance of "root shadows" is still debatable. Although the presence of calcareous deposit in the glands at the roots of the lungs is usually obvious, the interpretation of the radiating shadows is a matter still under discussion. They may be due to peribronchial thickening, caused by the

formation of fibrous tissue, or may merely represent the shadows cast by the branches of the pulmonary artery.

A film is not of crucial value in determining the presence or absence of early disease; slight diminution of translucency of one apex may be due to an old arrested lesion, or, on the other hand, there may be definite physical signs of active disease, without abnormalities being found on X-Ray examination. The heart shadow is often narrow and vertical in tuberculosis. Displacement of the heart due to pulmonary fibrosis or to affections of the pleura is clearly indicated. A good film may also give valuable information as to the extent of lung involved and as to the presence of complications, such as effusion, pneumothorax or bronchiectasis. As the X-Rays only cast shadows lacking in all pictorial details, tuberculous shadows cannot always be distinguished from those due to other pulmonary lesions, and, further, early disease may not obstruct the passage of the rays. It is thus clear that undue reliance must not be placed on the X-Ray findings, which should always be interpreted in connection with the history, symptoms and physical signs of the case. The X-Rays, although often of great help, do not afford a simple road to diagnosis or supply infallible evidence in determining the nature of an obscure case. On the other hand, they are absolutely essential in the determination of the suitability of a case for artificial pneumothorax treatment and in controlling its application.

Complications and Sequelæ.—Compensatory emphysema is common in chronic fibroid disease, but bronchiectasis occurs less frequently. Gangrene of the lung is not often observed. Colds and catarrhal affections of the respiratory passages are frequent in sufferers from tuberculosis, and lobar pneumonia may develop as a complication. Bronchitis often occurs, due either to spread of the tuberculous process or to a secondary infection. In some instances asthma appears for the first time after tuberculosis has become manifest. A tuberculous abscess occasionally forms about a rib or costal cartilage.

Small areas of dry pleurisy are present at some stage in nearly every case; a serous pleural effusion is common, and an empyema may develop as the result of a mixed infection, or from the tubercle bacillus alone. Pneumothorax may occur as an early complication, or late in the disease, generally from rupture of a caseous focus just under the pleura; this frequently progresses to the formation of a pyo-pneumothorax. The deposition of tubercle bacilli from the expired air and sputum may lead to secondary foci in the larynx, trachea and epiglottis, or more rarely in the pharynx, tonsils, base of the tongue or nose. Swallowing of sputum containing tubercle bacilli gives rise to gastro-intestinal complications in many cases. The most common site of tuberculous ulcers is the terminal portion of the small intestine, but the appendix may be affected, and the connective tissue around the caecum is sometimes matted and thickened to form a palpable mass (hypertrophic tuberculoma). Tuberculous peritonitis is not common in adults and is usually secondary to intestinal lesions. The stomach is very rarely ulcerated, but an atrophic gastritis may occur in advanced cases. Fistula-in-ano and ischio-rectal abscess are comparatively common complications.

Small vegetations may be found post mortem in the heart on the aortic and mitral valves, but these are usually due to some terminal infection.

Fatty degeneration of the myocardium occurs as a result of toxæmia, and infection by direct spread along the lymphatics may lead to serous or purulent pericarditis. The peripheral circulation is not infrequently poor, chilblains are common, and cachectic purpura may be seen. Lardaceous degeneration as a consequence of chronic tuberculosis is not so common nowadays as formerly, but when present may affect the liver, spleen, intestines, lymph glands and kidneys.

The genito-urinary complications include lesions in the kidneys, bladder, epididymis and prostate. If the suprarenal body is affected Addison's disease will usually develop. Spinal caries is occasionally observed. A peripheral neuritis may form part of the lesions occurring with marked cachexia. Generalised dissemination of the tubercle bacilli by the blood stream is followed by tuberculous meningitis.

Course.—The course pursued by pulmonary tuberculosis is variable, depending upon the clinical type of the disease. In acute miliary tuberculosis, death may occur in from 1 to 3 weeks from toxæmia or generalisation of the lesions. In acute caseous tuberculosis, death usually results in from 1 to 6 months. In chronic fibro-caseous tuberculosis, the disease may be completely arrested, or after a temporary arrest may become active at intervals and again become arrested under suitable treatment; in other instances it progresses steadily to a fatal termination. In fibroid tuberculosis the disease may become completely arrested or smoulder quietly for many years.

Apart from the question of the expectation of life, various stages of tuberculosis are described based upon anatomical lesions, toxæmia and functional disablement. The most important of these are as follows :

1. **THE TURBAN-GERHARDT CLASSIFICATION.**—An anatomical classification based upon the extent of lung tissue involved. Three stages are described. *Stage 1.* Early cases in which physical signs, if unilateral, only extend from the apex to the second rib, and, if bilateral, are limited to the supra-clavicular and supra-spinous regions. *Stage 2.* The signs, if unilateral, do not reach lower than the fourth rib, and, if bilateral, are situated above the second ribs. Excavation is not present in this stage. *Stage 3.* This includes more extensive lesions or localised ones in which excavation is present.

2. **SIR ROBERT PHILIP'S CLASSIFICATION.**—Both the extent of lung tissue involved and the degree of toxæmia present are taken into consideration. Twelve stages are described, which are indicated by the following signs :

L_1 , L_1s , L_1S , and l_1S ; L_2 , L_2s , L_2S , and l_2S ; L_3 , L_3s , L_3S , and l_3S . L_1 , L_2 , and L_3 represent lung involvement to the extent of stages 1, 2 and 3 respectively, according to the Turban-Gerhardt scale. s applied to these letters indicates that there is only slight systemic disturbance, whereas S signifies marked systemic disturbance; and the signs l_1S , l_2S and l_3S show that the systemic disturbance is excessive in relation to the lung involvement.

3. **INMAN'S CLASSIFICATION.**—This is based solely on the temperature in relation to exertion.

Stage 1. The patient is febrile when resting. *Stage 2.* The patient is resting afebrile, but ambulant febrile. *Stage 3.* The patient is ambulant afebrile. *Stage 4.* The patient is working afebrile.

The course taken by tuberculosis of the lung may lead to several terminations. These are—(1) permanent arrest, either by fibrosis prior to caseation,

or, if the latter has occurred, by calcification and fibrosis; (2) incomplete arrest, as shown by the persistence of tubercle bacilli in the sputum, or by slight degrees of pyrexia on over-exertion; (3) rapid extension, here the disease spreads, and the toxæmia is out of all proportion to the extent of the lesions; (4) death, this may result from the pulmonary lesion or from complications. The former may prove fatal as the result of progressive asthenia or cardiac failure, from asphyxia due to acute miliary tuberculosis or hæmoptysis, or in a small proportion of cases directly from loss of blood in repeated hæmoptysis. The complications that most often prove fatal are meningitis, enteritis, laryngitis leading to dysphagia and starvation, or pneumothorax. Intercurrent diseases, such as pneumonia, influenza or diabetes, are occasionally the cause of death.

Diagnosis.—This is easy when definite signs are present in the lungs, and when tubercle bacilli are found in the sputum. On the other hand, the diagnosis of early cases may present one of the most difficult problems in clinical medicine. Tuberculosis may be suspected on account of symptoms, although the physical signs are indefinite. The conditions which most frequently lead to doubt are dyspepsia, neurasthenia, debility, visceroptosis and intestinal stasis, oral sepsis, tachycardia associated with early Graves' disease or heart disorders, chlorosis, affections of the nose and throat, and in children enlargement of the bronchial glands or acidosis. The history and symptoms are of great importance in these cases, and a careful examination should be made of each system. A test meal, opaque meal, or blood examination may be required before the correct diagnosis is established.

On the other hand, there may be definite signs of disease in the lungs which have to be differentiated from those produced by other conditions simulating tuberculosis. The cases included in this group embrace the majority of pulmonary lesions, especially chronic bronchitis, fibrosis, bronchiectasis, asthma, emphysema, apical catarrhs and collapse, pleurisy, new-growths and cysts. Diagnosis depends upon the history and course of the disease, together with a careful record of the physical signs in the chest, examination of the sputum for infecting organisms, and in some cases the determination of the Wassermann reaction or an X-Ray examination.

When the diagnosis still remains doubtful the patient should be placed under observation, and a series of examinations carried out, the object of which is to determine whether or not active tuberculosis is present. The temperature should be observed with the patient in bed, a daily rise to 99° F. or a swing of 1°·5 to 2° below normal being suspicious. The sputum should be examined repeatedly for tubercle bacilli by the ordinary method, and if not found the antiformin process should be carried out. The albumin test may also be employed.

Before applying any tuberculin tests the blood may be examined serologically. The use of the Arneth blood count in diagnosis has been referred to on page 1173. The complement-fixation test has proved disappointing, and in the present form does not afford reliable criteria of activity or quiescence.

The stability reaction of the blood (sedimentation test), *i.e.* the rate of sedimentation of the erythrocytes in blood diluted with sodium citrate solution, is affected in this disease. In active cases the sedimentation rate is increased, but this reaction is not specific. It is also present in other conditions such

as pregnancy, carcinoma, syphilis, and acute infections. The test is therefore of little or no value in diagnosis, but it affords some indication of the degree of activity, and may assist in determining the form of treatment.

It has also been used as a guide to prognosis, since it is affirmed by some that arrest should not be considered as firmly established until the sedimentation rate has returned to normal. This may not occur until some time after the usually accepted clinical symptoms and signs of activity have disappeared.

THE TUBERCULIN TESTS.—1. *Cutaneous (the Pirquet reaction).*—Scarifications are made on the skin of the forearm through a drop of Koch's old tuberculin, human and bovine, and through a drop of saline as a control. A positive reaction is shown by the formation of a slightly raised, reddened papule at the site of the scarification through one or other varieties of tuberculin, whereas the control is not affected. Unfortunately, except in the first two years of life, this affords no indication of active disease, but only reveals the presence of previous infection with resulting tuberculin sensitiveness. A positive reaction is therefore given by the majority of adults. The graduated Pirquet is said to give an indication of the activity of the disease. In this process four scarifications are made through old tuberculin of strengths 1, 4, 16 and 64 per cent. respectively, and the resultant sizes of, and the differences in size between the papules, are measured and compared with a table.

2. Mantoux's intracutaneous test—an injection of 0.1 c.c. of a 1 in 10,000 dilution of old tuberculin (0.01 mgrm.) is injected intradermally. If no reaction occurs, the injection is repeated in a week, with 0.1 c.c. of 1 in 1000 dilution (0.1 mgrm.). A positive reaction is shown by a red areola, with some œdema and occasional vesiculation.

3. *Calmette's ophthalmic reaction.*—A drop of 1 per cent. old tuberculin is instilled into one conjunctival sac. A positive result is shown by the development of conjunctivitis in from 3 to 12 hours. This test also affords no indication of the activity of the disease, and, as there is some risk of permanent damage to the eye, it is not usually carried out in this country.

4. *The subcutaneous test.*—The patient must be apyrexial, and must be kept in bed— $\frac{1}{10}$ mgrm. of old tuberculin is injected subcutaneously, and its effect determined. The reactions that may develop are—(a) local, an inflammatory swelling at the side of the injection; (b) focal, an increase of the signs observed at the seat of disease in the lungs, such as the temporary appearance of a few râles at one apex. This is the most important; (c) general, as judged by a rise of temperature and sense of malaise. The temperature should be charted 4-hourly after the injection, and a rise to over 99° F. indicates a positive reaction. If no reaction follows this initial dose, larger injections are given at intervals of 2 or 3 days, in this sequence: $\frac{1}{10}$, $\frac{1}{5}$, 1, 5 and even 10 mgrms.

This test has the drawback of the two former tuberculin tests, that it does not indicate activity of disease, and it has the additional disadvantage that it may cause a quiescent pulmonary focus to light up and spread, and so cause irreparable damage. It is therefore wise to avoid it in cases of suspected lung disease.

Finally the X-Rays may afford some assistance in the diagnosis of early cases with doubtful signs, and may also assist in the differential diagnosis of tuberculosis from other lung diseases with well-marked signs.

Prognosis.—A number of factors must be critically considered in the determination of the prognosis in pulmonary tuberculosis.

A marked family incidence generally suggests an unfavourable course, though this rule is not invariable.

Personal history.—Chronic alcoholism is serious, chiefly because the régime of treatment is then peculiarly irksome, while the digestion and powers of resistance are often impaired in alcoholics. Tuberculosis in syphilitics frequently assumes a fibrotic type, and its course may be beneficially influenced by anti-syphilitic treatment. The outlook is grave when tuberculosis is conjoined with diabetes. Congenital heart disease and pulmonary stenosis are unfavourable factors; but hypertrophy of the heart and mitral stenosis are said to be beneficial.

The prognosis is very grave in infants and young children; but slightly less serious up to the age of 20. Between 20 and 50 age has little influence; but in later years the outlook becomes progressively less favourable.

Apart from the effects of pregnancy and exposure, sex plays no important part.

Freedom from financial embarrassment improves the prognosis, inasmuch as advice can be sought early, and treatment carried through thoroughly.

Marriage often leads to a breakdown in arrested cases, and induces more rapid spread of active lesions.

Persistence in an unfavourable occupation, or return to it after completion of institutional treatment, affects the prognosis adversely.

Poor chest development and the "habitus phthisicus" are usually bad prognostic signs, although tuberculosis often runs a rapid course even in patients with good physique.

Patients with resolute and persistent personality are more likely to persevere with treatment and to recover, than those of weaker moral fibre.

The prognosis is greatly affected by the type of the disease—acute miliary tuberculosis is usually rapidly fatal, whereas an acute caseous tuberculosis, although the prognosis is very grave, recovery may occur. In fibro-caseous tuberculosis the prognosis is most uncertain and difficult to forecast. Every factor must be carefully considered, and the response to treatment noted. The best outlook is in fibroid disease, which often undergoes complete and permanent arrest. The prognosis is usually fair in hilum tuberculosis, but acute and rapid spread sometimes occurs.

SYMPTOMS IN THEIR RELATION TO PROGNOSIS.—Persistent cough, by exhausting the patient and disturbing sleep, is often unfavourable.

The amount of sputum is usually dependent upon the type of disease and upon the presence of secondary infection, and may therefore be of value in prognosis.

The significance of tubercle bacilli in the sputum.—The figures obtained at the Midhurst Sanatorium, over a period of 8 years, in which the after-history of the patients was traced for the ensuing 6 years, show that the prognosis is best in "closed" cases; but that it is nearly as good in those cases in which the tubercle bacilli disappear from the sputum during the sanatorium treatment. Persistence of bacilli in the sputum is an unfavourable sign. The actual number of bacilli in the sputum and the presence of "beading" have no definite prognostic significance.

Cases commencing with hæmoptysis progress more satisfactorily than

those with other modes of onset, chiefly because they are diagnosed earlier. Hæmoptysis occurring later may exert an unfavourable influence, either indirectly by spreading the disease into previously healthy portions of the lungs, or actually by the loss of blood.

If dyspnoea is not due to attacks of bronchial spasm, it has usually an unfavourable significance.

The temperature affords a clue to the type and activity of the disease, and is thus a valuable aid to prognosis. Profuse and persistent night sweats, or marked anorexia, especially when occurring early in the disease, are grave signs. Tachycardia due to toxæmia, and signs of cardiac failure, are of bad omen. The blood pressure is thought by some to be a useful guide, systolic figures below 100 mm. Hg being unfavourable, whereas a rise of pressure may be associated with amelioration of the disease. In fibroid lesions the pressure may be raised throughout.

THE EXTENT OF PHYSICAL SIGNS.—The activity of disease rather than its extent is the important factor in determining prognosis. The development of compensatory emphysema is of value only as an indication of fibrosis in the tuberculous portion of lung, and therefore of chronicity.

THE INFLUENCE OF COMPLICATIONS ON PROGNOSIS.—Generally speaking, the presence of complications increases the gravity of the disease. Involvement of the larynx is a very serious complication, especially when accompanied by dysphagia; but complete recovery may take place if the pulmonary lesion is quiescent. In early cases spontaneous pneumothorax occasionally acts favourably; but when it develops in association with extensive tuberculosis, and especially if it progresses to pyo-pneumothorax, it is almost invariably fatal.

Pleural effusion often has a beneficial influence by diminishing the movements of a lung in which there is an early tuberculous focus.

Secondary catarrhal affections tend to increase the cough and expectoration, and may lead to further spread of the disease.

Meningitis is almost invariably fatal. Tuberculous peritonitis or enteritis is a very grave complication, but fistula-in-ano often occurs in chronic cases, and exerts no marked deleterious effect. Involvement of the genito-urinary system increases the severity of the disease, especially if the kidneys or bladder are affected. If the epididymis alone is involved the prognosis is not materially affected, as the lesion can be dealt with surgically, although the administration of a general anæsthetic may cause spread of the pulmonary disease. For this reason when operations are urgently needed on these patients, gas and oxygen, local or spinal anæsthesia should be insisted on.

As shown by the figures obtained at the Midhurst Sanatorium, a fairly accurate guide to prognosis is afforded by observing the condition of the patient on admission to the sanatorium, and his response to treatment. Even in the most favourable cases, which are diagnosed in an early stage, and progress satisfactorily under treatment, the mortality rate is six times greater after discharge from sanatorium than it is for the remainder of the population of England and Wales for the same age periods; whereas in the cases of advanced disease the mortality rate is thirty-eight times greater than for the average population. As the most critical time is during the two or three years succeeding discharge from sanatorium, the prognosis is largely affected by the conditions of life during this period.

It seems probable that the rate of sedimentation of the erythrocytes (see p. 1179) may prove to be a valuable aid to prognosis. A persistently rapid rate is unfavourable.

Treatment.—Prophylactic.—The prophylaxis of tuberculosis involves a consideration of public health questions dealing with the purity of the milk supply, the infection of meat, sanitation and housing, the early diagnosis of tuberculosis, the examination of contacts, and the segregation of "open" cases. Inoculation with the B.C.G. vaccine (attenuated living bovine bacilli) has not met with favour in this country. All these questions are considered in the general article on Tuberculosis.

Curative.—This varies with the type and stage of the disease. In all acute or febrile cases treatment should be commenced at home or in a nursing home or hospital, where the patient can be under careful observation in bed. The various forms of treatment which may be considered are—(1) sanatorium treatment; (2) home or institutional treatment; (3) dietetic treatment and personal hygiene; (4) climatic treatment; (5) graduated rest, exercise and labour; (6) medicinal treatment; (7) specific measures; (8) operative treatment; (9) symptomatic treatment.

1. SANATORIUM TREATMENT.—This constitutes the best mode of treatment for early and for certain types of chronic disease; but is totally unsuited for acute febrile or very active cases. The advantages obtained are—(a) the patient learns the most suitable mode of life, and the methods employed to check the spread of the disease; (b) the housing is specially designed and the climatic conditions are good; (c) the dietary is abundant and adapted to the patient's needs; (d) there is constant skilled medical supervision, and the daily routine is adapted to the actual physical condition of the patient.

On arrival a newcomer is kept in bed for a few days in order that his resting temperature may be observed, and the necessary examinations carried out. If there is pyrexia, rest in bed must be enforced until the temperature falls to normal. If the temperature rises above 99° F. when the patient is up, return to bed is usually necessary. The routine of sanatorium treatment varies in different institutions, the most important divergence being whether or not a system of "graduated exercise" is employed. In nearly all an hour's recumbent rest is enforced before lunch and dinner.

After three months' stay it is usually possible to decide whether the patient is responding to treatment, and, if so, it should, if possible, be prolonged for at least another three months, or until the sputum is free from tubercle bacilli.

2. HOME AND INSTITUTIONAL TREATMENT.—Treatment at home, in nursing homes or in special hospitals, is essential in early cases with fever, and in cases in which it is necessary to establish the diagnosis. Home treatment is also usually necessary on return from sanatorium or climatic treatment, if arrest is incomplete. An endeavour should always be made to carry out the principles inculcated at the sanatorium, and the patient should be under regular medical supervision. Advanced cases are best looked after in special institutions.

3. DIETETIC TREATMENT AND PERSONAL HYGIENE.—It is desirable to graduate the diet in each case so that the patient is restored to the previous maximum weight; but, in order to accomplish this, the food should be slowly increased and all ideas of enforced overfeeding discountenanced. A total

calorie value of 3000 to 3500 is usually ample ; but, if the patient is performing heavy work, as much as 4000 may be necessary. Meat, fish, eggs and fats are usually well tolerated. It is not often necessary to give large quantities of milk when the patient is on a full dietary. If extra food is required, the protein may be increased by raw meat sandwiches, and additional carbohydrates may be taken.

In all cases in which there is expectoration the patient should be clean-shaven. Great care must be taken in the disposal of sputum to ensure that it does not become dry, and that flies do not have access to it. All patients who are up should carry special sputum flasks, while those who are in bed should have sputum cups suitably covered and containing disinfectant. The sputum should be burnt, or, if this is impossible, it should be emptied into the water-closet after disinfection with carbolic acid or other simple or cheap disinfectant.

Smoking is best avoided in cases of active disease or laryngeal tuberculosis, and in no instance should inhaling be allowed. Woollen under-garments should be worn ; but all excess of clothing is harmful.

4. CLIMATIC TREATMENT.—This is undoubtedly of value in carefully selected cases. The climatic resorts fall into three groups—mountain, marine and inland.

The mountain resorts.—In Europe the most suitable places are found in Switzerland. Among these are St. Moritz (6090 feet), Arosa (6000 feet), Davos (5150 feet), Montana (5000 feet) and Leysin (4690 feet). In America the most celebrated resorts are in the Rocky Mountains at Colorado Springs (5000 feet) and Denver (5000 feet), or in the Andes or Adirondack Mountains. The advantages of high altitudes consist in the stillness, purity and rarefaction of the air, and the greater diathermancy of the atmosphere to the sun's rays. Metabolism and the general circulation are thereby increased.

High altitudes are suitable for early cases which are afebrile, or for quiescent cases of more advanced type. Contra-indications are recent hæmoptysis, active disease with fever, extensive fibrotic lesions and complications such as emphysema, asthma, cardio-vascular lesions or nephritis.

Marine and coast resorts.—Among the important coast resorts in the British Isles are Bournemouth, the Isle of Wight, Torquay, Falmouth, Llandudno, Penmaenmawr, Scarborough, Mundesley and the various seaside towns in Thanet. Further afield are the French and Italian Riviera, Maderia, the Canary Isles, Morocco, Algiers and Egypt. The climate tends to be warm, moist and equable, and the amount of ozone is probably increased. These resorts are especially suitable for cases of more advanced and active disease, and for those complicated by hæmoptysis, bronchitis, emphysema and laryngitis.

Inland resorts.—These are to be found on the English and Scottish moorlands. The climate of California, the South African veldt, and parts of Australia and New Zealand are admirably suited to this disease, especially for arrested or early uncomplicated cases ; but the laws against the admission of tuberculous patients are strictly enforced at all of them.

Sea voyages.—These are contra-indicated for all except completely arrested cases, owing to the lack of fresh air in cabins, the possibility of sea-sickness, and the difficulty of obtaining suitable treatment if the disease advances.

5. GRADUATED REST AND EXERCISE.—Treatment in bed is necessary so

long as there is fever, and if the raised temperature is persistent, "absolute rest" should be enforced. This consists in keeping the patient recumbent in bed, sufficiently well covered to prevent any muscular contraction from chill, while feeding and washing are attended to by the nurse, and the use of the bed-pan and slipper for evacuations is insisted upon. When the temperature becomes normal the patient is allowed up for varying periods, commencing with 1 hour daily, and increasing slowly to 6 or 8. If still apyrexial, walking exercise of 1 or 2 miles or more daily can be allowed.

The system of "graduated exercise" which Paterson instituted at the Frimley Sanatorium has proved of great value. There are six grades, the first and lightest consisting of walking up a slope carrying a light weight such as a basket of earth, while the sixth and heaviest involves hard manual labour with a pickaxe or shovel for 6 hours daily. This system is based on the principle that muscular exercise leads to the discharge of tubercle toxins from the pulmonary focus, and by liberating these in gradually increasing doses, a condition of active immunity is induced. A careful watch must be kept during this controlled process of auto-inoculation to prevent excessive doses of toxin being discharged, which are early indicated by rise of temperature and of pulse-rate, headache, increased cough and expectoration, lassitude and malaise. If such occur, the patient should be put back to bed for a few days, and when the condition has subsided the graduated exercise may be resumed at the grade which induced the over-inoculation or that immediately below it.

6. MEDICINAL TREATMENT.—No specific drug has yet been discovered for the treatment of tuberculosis. Amongst the medicines in most general use are :

(a) Cod-liver oil.—This may be administered by the mouth in doses up to 2 ounces daily, or 0.5 to 2 c.c. of a 3 per cent. solution of sodium morrhuate may be injected subcutaneously once or twice a week (Rogers). The cod-liver oil may be of value either on account of its fat-soluble A vitamin content, or, as suggested by Rogers, it may assist by dissolving the capsules of the tubercle bacilli and so facilitating their disintegration.

(b) Creosote.—This may be given in doses of ℥ ij to iij three times a day after food, either in combination with cod-liver oil, or in capsules. It should be discontinued if gastric disturbance or hæmoptysis ensue.

(c) Hypophosphites.—These are not so generally used as formerly and, beyond their "tonic" effect upon the nervous system, have no demonstrable influence upon the pulmonary lesion.

(d) "Nascent" iodine.—With the idea of liberating free iodine in the tissues, potassium iodide grs. xxx is administered after breakfast in half a pint of water, and throughout the day 3 to 5 ounces of chlorine water are consumed with lemonade. This treatment is of value in certain chronic fibroid cases, but it often produces no appreciable results, and may cause dyspepsia.

(e) Arsenic.—Liquor arsenicalis ℥ ij to iij by mouth, or sodium cacodylate gr. $\frac{1}{2}$ to $\frac{1}{2}$ subcutaneously, are of value in some cases associated with anæmia. Salvarsan or novarsenobillon, administered intravenously, is useful in chronic cases complicated by syphilis.

(f) Inhalations.—Disinfectant drugs when inhaled often check cough, lessen expectoration and improve the general condition of the patient. Lees's

inhalation, or some modification of it, is of value. It consists of creosote, parts 2; acid. carbol. 2; liq. iodi mitis, 1; sp. ætheris, 1; and sp. chlorof. 2. About 6 drops an hour are placed upon a Burney-Yeo mask, which should be worn almost continuously throughout the day.

(g) Calcium is often given by the mouth in the form of collosol calcium in doses of 1 drachm three times a day; or intramuscularly, as calcium sandoz 5 c.c. once a week. Parathyroid extract is sometimes administered at the same time.

(h) There has been a revival of interest in preparations of gold in the treatment of this disease, notably by Mollgaard, who uses sodium aurothio-sulphate, to which the name of sanocrysin has been applied. It is now administered in smaller doses than when it was first introduced. The initial dose is usually 0.05 gramme dissolved in sterile saline solution and injected intravenously. The second dose is given 5 days later, and is as a rule 0.1 gramme. If no reaction occur, the dose is increased to 0.25 gramme, and later to 0.5 gramme or at most 0.75 gramme, the intervals being extended to a week. The total amount given in a course is usually 3 grammes, or sometimes up to 5. The course may have to be interrupted owing to reactions, chiefly fever, albuminuria, diarrhoea and skin manifestations.

7. SPECIFIC MEASURES.—(a) *Active immunisation*.—Tuberculin and tubercle-vaccines.

The tuberculin treatment has not fulfilled the high hopes held out on its introduction by Koch. There are now numerous forms of tuberculin available, indicated by certain letters, and falling into three groups. (1) Those containing the exo-toxins only. These include Koch's old tuberculin T., O.T., and T.O.A., Denys' bouillon filtré (B.F.) and albumose-free tuberculin, T.A.F. (2) Those containing the endo-toxins chiefly, such as Koch's "new" tuberculin, T.R. (3) Mixtures of endo- and exo-toxins, the most important of which are Koch's bacillary emulsion, B.E., the sensitised bacillary emulsion, S.B.E. and Béranek's tuberculin, T.Bk.

The Therapeutic Substances Act, 1925, restricts the term "tuberculin" to the first of these groups, and recommends the name "tubercle vaccine" for any substance obtained directly from the bacterial bodies.

Tuberculins and tubercle-vaccines may be prepared from human or bovine bacilli; if from the latter the letter P. (perlsucht) placed before the letters indicating the variety of tuberculin, signifies its origin, e.g. P.T. In administration, some aim at producing reactions and establishing tuberculin tolerance by giving large doses at fairly frequent intervals; others believe in minute doses at longer periods, the chief object being to avoid the production of any reaction. The actual doses are either measured in milligrammes of dried tubercle bacilli, or in cubic centimetres or cubic millimetres of the fluid tuberculin. The usual method is to measure the doses in cubic centimetres or fractions thereof, and to make the necessary dilutions in a series of bottles. Smaller initial doses should be used with a strong tuberculin such as the B.E. than with the weaker ones such as the T. or A.F. Thus, if adopting minute doses $\frac{1}{100,000}$ mgrm. of B.E. would be a suitable initial dose, then for T.R. $\frac{1}{100,000}$ mgrm. would be used and $\frac{1}{10,000}$ mgrm. of T., B.F., or A.F. As the different tuberculins are supplied by the makers in varying strengths, 0.001 c.mm. of the original fluid is equivalent to the above doses.

Those who believe in minute doses commence with 0.001 c.mm. and work

up to 0.1 c.c., whereas others commence with 0.5 to 1 c.mm. and increase to 1 c.c. The tuberculin should be injected subcutaneously, and a careful observation kept for local, focal and general reactions. Tuberculin, if used injudiciously, can be productive of harm. At Midhurst Sanatorium it was tried for some years, and no better ultimate results were obtained than in the "non-tuberculin" years. It seems wise, therefore, to use tuberculin only in very carefully selected cases, thus T.R. does at times appear beneficial in chronic tuberculosis, promoting the formation of fibrous tissue and leading to the disappearance of tubercle bacilli from the sputum.

Recently various attempts have been made to remove as far as possible the fatty and waxy constituents from the tubercle bacilli before preparing a vaccine from it. The best known of these is the *diaplyte* vaccine of Dreyer. Much and his collaborators have employed partial antigens or partigens derived from tubercle bacilli or in varying combinations. Some good results are on record from both of these methods, but on the whole their use has so far been disappointing.

(b) *Passive immunisation*.—The various serums such as those prepared by Marmorek and Maragliano have not proved successful, and this applies to the "contra-toxin" of Mehnarto and the "I.K." (immune bodies) of Spengler.

8. OPERATIVE TREATMENT.—(a) *Artificial pneumothorax*.—This mode of treatment is now becoming more generally adopted in selected cases. It is not, as a rule, indicated in early disease and in cases progressing favourably, but is sometimes employed as an early and primary method of treatment in such cases. In extensive bilateral disease it may be dangerous. If old and dense pleural adhesions are present, it is impracticable. If there is much emphysema or cardiac embarrassment, it involves risk. Only a relatively small group remains which comprises cases in which the disease is mainly unilateral and those which remain febrile in spite of prolonged bed treatment. It is also of value in certain cases of repeated severe hæmoptysis. Tuberculous laryngitis or enteritis are not contra-indications, providing that other conditions are suitable. Nitrogen or sterile air is introduced into the pleural cavity, and the lung allowed to collapse. The method of induction of artificial pneumothorax is as follows: A preliminary subcutaneous injection of $\frac{1}{2}$ grain of omnopon is given half an hour before the start. The patient lies on the sound side with the head low and supported on a pillow. A second pillow is placed under the chest to expand the intercostal spaces. The skin and the tissues down to the pleura are anæsthetised with 2 per cent. novocain solution after the application of iodine. The site usually chosen is in the sixth intercostal space in the mid-axillary region. A special pneumothorax needle, attached by a rubber tube to the pneumothorax apparatus, which is carefully examined to see that it is in proper working order, is then pushed through the intercostal space until the pleural cavity is reached. The apparatus is then adjusted so that the intrapleural pressure can be observed. No air should be introduced until the manometer show a normal negative pressure range with inspiration, of 5 to 10 or more cm. of water. This is the test of entry into the pleural space, and when this is established 200 to 300 c.c. of sterile air may be allowed to enter the pleural cavity. The final pressures are then recorded and the needle is withdrawn. A refill is given next day and again after two more days, the quantities of air introduced being determined by the final pressures, which should be kept

slightly negative. Subsequent refills are gradually spaced out to a week, then ten days and later to two, three and four weeks' intervals. The tendency now is to maintain the collapse for two or three years or even longer. If the condition of the patient is satisfactory, re-expansion may then be permitted cautiously. It should be remembered that after expansion pleural adhesion almost invariably occurs and the treatment by artificial pneumothorax cannot be repeated. In a few cases of bilateral disease, which is active but not very extensive in either lung, a cautious use of bilateral artificial pneumothorax has proved practicable and helpful, but very great care is necessary.

There are certain dangers in the procedure. These are now rare, and they can usually be prevented by careful attention to the technique. Death has occurred from pleural shock when the needle has reached the pleura and before any air has been introduced. Adequate anaesthesia of the pleura is the only known method of eliminating or minimising this risk. If the lung is adherent to the chest-wall, owing to pleural adhesions, or if the needle is pushed in too far, it may be inserted into the lung or into a pulmonary cavity; the manometer will then show a swing above and below the zero line instead of entirely below it. Under these circumstances, no air should be allowed to enter. The needle may be inserted into a blood vessel. In this case the manometer pressure will rise above zero, and blood may appear in the glass section inserted in the rubber tube leading from the manometer to the needle. The needle should be withdrawn immediately, lest air should enter the vessel.

If the pleura is found to be adherent at the site of the first puncture, another attempt may be made elsewhere, e.g. just below the inferior angle of the scapula. This spot may be selected for the initial puncture in left-sided cases where there is marked cardiac displacement. In cases in which localised band or cord adhesions prevent effective collapse, it is sometimes possible to cut them by electrocautery or diathermy through an operating thoracoscope. This is called internal pneumolysis.

(b) *Evulsion (exairesis) of the phrenic nerve*.—This is now often performed in order to produce basal collapse, but it helps to produce relaxation at the apex and may aid in the contraction of a cavity. Division alone is not sufficient; it is desirable to remove as long a stretch of the nerve as possible.

(c) *Thoracoplasty*.—If owing to adhesions it is impossible to collapse the lung temporarily by an artificial pneumothorax, permanent collapse may be considered. This can be effected in suitable cases by removal of a sufficient amount of the ribs from the first to the tenth to allow the chest-wall to fall in and so permit the lung to collapse. This may be done in one or two stages, and under local or general anaesthesia or both combined.

(d) *Apicolysis (extrapleural pneumolysis)*.—Successful local collapse can sometimes be attained by introducing some extraneous material like paraffin between the chest wall and the parietal pleura over a local area of disease, or a cavity which is not too near the pleura.

9. SYMPTOMATIC TREATMENT.—When cough is ineffective it may be relieved by a sedative lozenge or linctus containing heroin or codeine, or by the well-known liquorice lozenge. If there is difficulty in bringing up the sputum, a simple saline mixture is of value, such as sodii bicarb. grs. x, sodii chlorid. grs. ii½, sp. chlorof. ℥ 10, and aq. anisi ad ʒi.

Pain in the chest is usually alleviated by local application of pigmentum iodi, liniments, mustard leaves or other counter-irritants.

Night sweats.—The windows should be widely opened at night. A pill containing zinc. oxid. grs. iij and ext. belladonn. succ. gr. $\frac{1}{4}$ is often of value. Picrotoxin, agaricin and strychnine have also been used.

Fever.—Rest in bed up to the extent of "absolute rest" is the best means of lowering the temperature. Antipyretic drugs have no effect upon the course of the disease, but may alleviate malaise. Amongst these may be mentioned aspirin, cryogenin and pyramidon.

Slight hæmoptysis, in which the sputum is only streaked, calls for no special treatment. Moderate hæmoptysis, with expectoration of 3 or 4 ounces of blood, requires more active measures. The patient should be put to bed, a saline aperient administered, and if there is anxiety or alarm a sedative drug should be given, such as heroin or morphine. In profuse or persistent hæmoptysis the patient should be confined strictly to bed, and if it is known from which side the bleeding has occurred, it is best to lie on this side. If the cough is troublesome, or if the patient is alarmed, morphine gr. $\frac{1}{4}$ to $\frac{1}{2}$, or heroin gr. $\frac{1}{15}$ to $\frac{1}{12}$ should be injected subcutaneously. The food is best given cold, and may be iced; no alcohol must be taken. A course of calcium lactate grs. x, t.d.s., may be commenced; but its action is somewhat uncertain, and should not be prolonged for more than 3 or 4 days at a time. If the bleeding persists, various other remedies should be tried, these include the inhalation of amyl nitrite, or the injection of hæmoplastin, coagulen ciba, horse serum, or emetine hydrochloride subcutaneously. Ergot and adrenaline are both contra-indicated. If the hæmorrhage is still unchecked, or is frequently repeated, the advisability of establishing an artificial pneumothorax must be considered.

Gastro-intestinal symptoms.—Anorexia or dyspepsia can often be relieved by changes in diet, or by the administration of suitable drugs. Alkalis and gentian are especially valuable, and when hypochlorhydria is present, dilute hydrochloric acid in large doses (M x-xxx) should be given well diluted after meals. Digestive ferments, such as taka-diastase or papain, may be required at times. All tendency to constipation should be checked by laxatives, and if diarrhœa develops, avoidance of diet leaving bulky or irritating residues should first be tried, before administering drugs containing lead, opium, bismuth or tannic acid.

Insomnia is often a troublesome symptom, and every endeavour should be made to obtain a good night's rest by administration of mild hypnotics, and by relieving distressing cough and pain.

The treatment of the complications of pulmonary tuberculosis is described under their respective headings. The after-care of patients discharged from sanatoria is an important subject, to which considerable attention is being devoted, and involves a consideration of the advisability of establishing training centres or colonies for consumptives.

THE PULMONARY MYCOSES (PNEUMONOMYCOSES)

A number of fungi produce pulmonary lesions. Considerable confusion exists in regard to their nomenclature, and at the present time it is difficult

to give accurate accounts of them. The pulmonary mycoses have one feature in common, in that they produce chronic pulmonary lesions practically indistinguishable clinically from those of the chronic forms of pulmonary tuberculosis.

Among the varieties of mycotic infection at present separated clinically may be mentioned—(1) Actinomycosis (Nocardiasis, Streptotrichosis); (2) Aspergillosis; (3) Blastomycosis; (4) Sporotrichosis; (5) Moniliasis; (6) Mucormycosis.

ACTINOMYCOSIS (NOCARDIASIS, STREPTOTRICHOSIS)

Ætiology.—The general characters of the streptothrix group of organisms are described in the section on Actinomycosis. It is now recognised that more than one of these may be pathogenic for man, and some authors give separate descriptions of the forms due to the various streptothrix organisms. At the present time there seems little advantage in so doing, since the important point in regard to treatment is to recognise that the morbid process is due to some form of streptothrix infection, the identification of the variety being a pathological refinement. The manner of infection is at present obscure. The organism is now believed to be present not infrequently in the alimentary tract, but the conditions favouring its invasion of the tissues are not known. A large proportion of cases show the first lesions in the head and neck regions, but primary pulmonary cases occur, and are probably more frequent than is generally recognised.

Pathology.—The streptothrix group of organisms produces an inflammatory reaction which leads to the formation of granulomatous tissue. This, like the granuloma of tubercle, is very liable to undergo secondary changes producing small areas of pus formation or leading to fibrosis. Unlike tuberculosis, however, streptotrichosis tends frequently to transgress anatomical limitations and spreads by contiguity. In the primary pulmonary cases the distribution of the lesions is at first very similar to that of tuberculosis, and the disease may extend in an identical manner. In the forms due to spread from other organs such as the liver, the base may be first involved, while in cases extending down from the neck the path of the infection is easily followed.

Owing to the tendency of the lesions to spread by contiguity, subcutaneous abscesses may form and simulate caries of the ribs. Pleural adhesion is the rule, but occasionally empyema results. When a subcutaneous abscess ruptures or is opened, the characteristic “sulphur granules” may be found, although this is not invariable. The skin around the sinuses which result is often puckered in a somewhat characteristic fashion.

Symptoms.—These are in general identical with those of the chronic forms of pulmonary tuberculosis, such as cough, expectoration, which may be offensive, dyspnoea, fever and night sweats. The occurrence of local abscesses under the skin or the presence of the parasite elsewhere may give rise to special features; but these are late developments in primary pulmonary cases.

Complications and Sequelæ.—These are usually due to the other localisations of the parasite; but, in addition, empyema and bronchiectasis may be mentioned.

Course.—This is progressive, and leads eventually to *asthenia*, emaciation and death.

Diagnosis.—This can only be established by the discovery and identification of the parasite in the sputum and the discharge. The characteristic "sulphur grains" are not invariably present, and may escape notice unless looked for carefully. In any obscure case of pulmonary disease in which tubercle bacilli are not found after repeated search, the possibility of streptotrichosis should be considered, and direct films should be specially examined.

Prognosis.—This is serious, although some cases respond well to treatment.

Treatment.—Large doses of potassium iodide should be administered, commencing with 5 or 10 grains three times a day, and increasing until the dose reaches a drachm or even more thrice daily. In addition, collosol iodine (Crookes) may be given intravenously in doses of 5 c.c. at least once a week. If the parasite grows well in culture, a vaccine may be prepared and employed cautiously, especially if the iodides do not act satisfactorily. A stock vaccine may be helpful in other cases. Surgical treatment of local abscesses or of empyema may be required.

PULMONARY ASPERGILLOSIS

Ætiology.—Infection of the bronchi and lungs sometimes occurs by the *Aspergillus fumigatus*, more rarely by the *A. nidulans*. The disease has been most frequently observed in France. It occurs among pigeon breeders and hair sorters and combers. The former acquire the disease from the process of artificial feeding, from grains in the mouth to the beak of the bird; the latter from the use of rye flour in cleaning the hair. Millers and farm labourers have also been the subjects of the disease.

Pathology.—The fungus induces nodular formations in the lung tissue somewhat resembling aggregated tubercles. Bronchitis, patchy lobular consolidation and fibrosis result. Emphysema, bronchiectasis and cavity formation may follow. A secondary aspergillosis may occur in chronic cases of bronchitis or lung disease, but is of little clinical importance.

Symptoms.—Primary aspergillosis produces symptoms similar to those of bronchitis, broncho-pneumonia or pulmonary tuberculosis, according to the localisation and degree of the lesions. The sputum may be blood-stained, or definite hæmoptysis may occur. There is generally wasting with irregular fever.

Course.—Acute broncho-pneumonic forms may be fatal in a few weeks or months. The chronic lesions may extend to years, and arrest with fibrosis is not uncommon.

Diagnosis.—The condition has to be differentiated from pulmonary tuberculosis, and from other varieties of pneumonomycosis. This depends upon the recognition of the fungus by microscopical and cultural examination of the sputum.

Treatment.—This consists in avoiding further infection, and giving large doses of potassium iodide as in streptotrichosis. Open-air measures and general tonic treatment are also to be recommended.

OTHER MYCOTIC INFECTIONS

Fungi of the genera, *Blastomyces* (*Oridium*, *Coccidioides*) and *Sporotrichum* are well known to produce cutaneous affections simulating chronic gummatous or tuberculous lesions. They may also give rise to pulmonary disease producing symptoms like those of tuberculosis.

Castellani has described various broncho-pulmonary conditions due to species of the genus *Monilia*, including the "tea-tasters' cough" and "tea-factory cough." Another fungus, *Mucor mucedo*, has been found in the sputum, and is regarded as pathogenic to man.

All these moulds produce bronchitic symptoms and mild infections, while more severe forms simulate pulmonary tuberculosis. The diagnosis in each case depends upon the recognition of the fungus, and the treatment recommended is large doses of potassium iodide.

SYPHILIS OF THE LUNGS

Ætiology.—Clinically recognisable pulmonary syphilis is a rarity; but syphilitic lesions occur in the lungs in both the congenital and acquired forms of the disease.

Pathology.—Even post mortem it is often difficult to establish the syphilitic nature of the pulmonary lesions found in cases of syphilis, owing to the fact that they tend to the formation of scars presenting no characteristic features.

Congenital syphilis.—The essential changes are—(1) Round-celled infiltration with eventual fibrosis, starting round the bronchi and spreading to the inter-alveolar framework; (2) periarteritis of the smaller arteries; and (3) desquamation and degeneration of the epithelium of the alveoli and bronchi. Gummata may be present, but are rare. Spirochætæ can be demonstrated in the lesions by Levaditi's method. The microscopic appearances comprise the "white pneumonia" of Virchow and an interstitial pneumonia, which is commoner, although both conditions are frequently associated. White pneumonia is found in premature or still-born infants, and in those dying soon after birth. The condition may be widespread or localised. The affected areas are firm, consolidated, smooth and greyish-white in colour. There are no interstitial changes, and the consolidation is due to the filling of the alveoli with desquamated, degenerating epithelial cells.

In the commoner interstitial form the lung is firmer, harder and darker grey in colour, and the connective tissue is mainly involved. To this condition the term "pancreatisation of the lung" has been applied by Rogers.

Acquired syphilis.—Syphilitic lesions of the bronchi have already been described in the section on diseases of the bronchi. Gummata may occur in or around the intra-pulmonary bronchi or in the lung tissue. They may be single or multiple, and vary in size from that of miliary granules to a hen's egg. They are said to be more common in the deeper parts of the lung near the roots and in the lower lobe. They undergo changes similar to those occurring in gummata elsewhere, but tend more to fibrosis and contraction than to softening. Owing to these secondary changes, the following

conditions may result: broncho-pneumonic processes, widespread fibrosis and contraction with pleural adhesion, bronchiectasis and occasionally excavation.

Symptoms.—Small gummata may be latent and give rise to no symptoms or signs. When fibrosis occurs, they are similar to those of pulmonary fibrosis from other causes. It is generally recognised that in rare cases a destructive process occurs, formally called "syphilitic phthisis," and almost exactly similar in its clinical manifestations to those of caseous or fibro-caseous tuberculosis.

Complications and Sequelæ.—Syphilitic lesions in the larynx, trachea or bronchi may complicate the course. Bronchiectasis has already been mentioned, and tuberculosis may occur as a complication.

Diagnosis.—This is often difficult and sometimes inconclusive. Obscure pulmonary signs in a syphilitic subject should arouse suspicion. The Wassermann reaction should be determined, and other indications of syphilis looked for in all fibrosing and destructive lung conditions when no tubercle bacilli are found in the sputum. The difficulty of diagnosis is increased by the association of syphilis and tuberculosis mentioned above.

Course and Prognosis.—Where the lesions are localised and can be recognised early, the course is favourable if anti-syphilitic treatment is applied. Where fibrotic changes occur, leading to bronchiectasis, the course is less favourable, and in the destructive form it is serious. An intercurrent tuberculous infection increases the gravity of pulmonary syphilis.

Treatment.—When a diagnosis of pulmonary syphilis has been established, vigorous anti-syphilitic treatment should be carried out. Its beneficial effect is undoubtedly promoted by open-air treatment. In cases where tuberculosis coexists with syphilis, anti-syphilitic treatment is strongly recommended, especially by French physicians.

NEW-GROWTHS OF THE LUNGS

Both simple and malignant tumours may occur in the lungs, the latter being the more common.

Ætiology.—Malignant tumours occur more frequently in the male sex; carcinoma is rare before the age of 40, but sarcoma may develop in earlier years. Simple tumours may arise at any age, but are found chiefly in adult life. The exciting cause is unknown. In some cases of malignant growth there is a history of thoracic trauma.

Pathology.—Simple tumours found in the lungs usually arise in the bronchial mucous glands or in the bronchi. They include adenoma, fibroma, lipoma and chondroma. Malignant tumours may be primary or secondary. The primary growths are carcinoma, sarcoma or endothelioma. Carcinoma arises either in the bronchi, as a columnar-celled growth, or in the alveoli as a spheroidal-celled carcinoma. A variety of bronchial new-growth formerly regarded as a lympho-sarcoma is now called an oat-celled tumour. It is derived from the basal cells of the bronchial mucous membrane. Squamous-celled growths of the bronchi are rare, and have been regarded as due to metaplasia, which is not uncommon in new-growth in this situation. Round-celled and spindle-celled sarcomata growing from the pulmonary connective tissue are met with, while endotheliomata are usually derived from the endo-

thelium of blood vessels and lymphatics, or from the pleura. A primary carcinoma of the breast, œsophagus or mediastinum may directly invade the lungs. Secondary carcinoma may have its primary focus in the breast, stomach, intestines, liver, pancreas or prostate, whereas a secondary sarcoma most often results from metastasis of a primary bony growth. Chorion-epithelioma and hyper-nephroma also give rise to secondary deposits in the lungs.

Primary malignant tumours are usually unilateral; but secondary growths are often multiple and diffuse. Dissemination in the lungs may occur by spread along the bronchi or vessels, and a condition of miliary carcinomatosis is at times produced. The pleura is often affected by direct extension. Infiltration of, or pressure upon, the mediastinal structures frequently occurs.

Symptoms.—Simple tumours are pathological curiosities and, as a rule, only produce symptoms when they cause destruction of a bronchus or press on mediastinal structures.

The early symptoms of malignant growths are slight, and consist of malaise with, perhaps, cough and expectoration. Later, when the growth becomes more extensive and exerts pressure on, or involves the larger bronchi, mediastinum or pleura, they are more noticeable. Pain, dyspnoea and loss of weight with cachexia usually develop, and the cough and expectoration are more marked. The latter is often of the typical "currant jelly" or "prune juice" appearance due to altered blood. Microscopically, groups of large fatty cells, or irregular epithelial cells may be seen. There is usually no definite physical signs until the tumour causes pressure upon the bronchi, mediastinum or deep thoracic veins or nerves. The chest-wall may bulge locally, owing to the presence of a growth near the surface, or it may be retracted if a main bronchus is obstructed. An actual subcutaneous swelling caused by the tumour eroding through the chest-wall may be visible. Enlarged veins often run across the chest, and one or other arm may be swollen or œdematous if there is mediastinal obstruction. Vocal fremitus is often unaffected; but is increased when the growth is near the surface, and diminished if pleural effusion has occurred. The percussion note over a moderate-sized tumour is impaired and may be extremely dull. The breath-sounds vary with the size and position of the growth, and with the displacement or pressure effects produced. They may be weak, or loud and stridorous. Adventitious sounds depend upon the presence of complications such as bronchitis. Some degree of fever often occurs. The supra-clavicular and axillary glands are not infrequently enlarged, and evidence of malignant disease may be present in other parts of the body such as the abdomen.

Complications and Sequelæ.—Bronchitis is nearly always present in some degree. Pulmonary collapse, fibrosis, bronchiectasis, emphysema, gangrene, hæmoptysis and pleural effusions are sometimes observed. The latter is frequently bloodstained. In cases of primary malignant disease of the lungs, secondary deposits may occur in other parts of the body.

Course.—This is progressive, the patient gradually losing strength and dying from cachexia or some intercurrent affection.

Diagnosis.—This is difficult in early cases, and not easy in some advanced ones. Difficulties may arise in connection with pulmonary tuberculosis, fibrosis and gumma of lung, aneurysm, pericardial and pleural effusion

and enlargement of the mediastinal glands due to Hodgkin's disease or tuberculosis. The whole body should be searched for evidence of malignant disease elsewhere. The sputum should be examined repeatedly for tubercle bacilli and for cellular elements, and an X-Ray examination made of the chest. By the stereoscopic method excellent evidence of pulmonary neoplasms is often obtainable. Lipiodol injection and X-Ray examination may demonstrate the obstruction of a bronchus by the growth which often presents a tapering or "rat-tail" appearance. Bronchoscopy may also serve to establish the diagnosis. Temporary artificial pneumothorax may be helpful in diagnosis, particularly in differentiating simple tumours in the periphery of the lung, growths in the mediastinum and in the chest-wall.

Prognosis.—Apart from those cases in which early recognition may in suitable conditions render lobectomy, with removal of the growth, possible, this is hopeless, death occurring in a few weeks, or being delayed for two or three years.

Simple tumours are often capable of complete removal with gratifying success.

In malignant growths lobectomy with complete removal of the growth is only practicable for cases recognised early in which there are no secondary deposits.

Treatment.—In cases unsuitable for lobectomy and radiation treatment this can only be palliative and symptomatic. Useless cough should be checked by sedative lozenges or a linctus. Dyspnoea due to pleural effusion may be relieved by tapping; but the fluid often reaccumulates rapidly. Pain should be relieved by analgesic drugs, and in the later stages those containing opium or its alkaloids may be required. Radon seeds are now extensively used; when practicable they are inserted into the growth through a bronchoscope. In other cases they may be introduced directly into the growth by thoracotomy.

PARAGONIMIASIS

Synonyms.—Pulmonary Distomatosis; Lung Fluke Disease; Endemic Hæmoptysis; Parasitic Hæmoptysis.

Ætiology.—(See p. 347).

Pathology.—The flukes settle down in the lungs and form burrows. These burrows may coalesce and give rise to cystic swellings, varying from $\frac{1}{2}$ to $1\frac{1}{2}$ inches in diameter. These in turn develop fibrous sheaths and may give rise to abscess formation or pleurisy. The adult fluke is hermaphrodite, and lays numerous eggs which measure $100 \times 70 \mu$. These are coughed up in the sputum, and are easily recognisable owing to their large size. The adult parasites are also occasionally found in the brain, liver, lymph glands and peritoneal cavity.

Symptoms and Complications.—The onset of symptoms, after infection has taken place, is insidious, with cough and expectoration. The latter is very constantly blood-stained, and there may be profuse hæmoptysis. Secondary pleurisy occurs when the cysts reach the surface of the lungs, causing pain. Examination may reveal no abnormal signs, at most there

are a few scattered râles, together with signs of dry pleurisy at one point. Later in the disease the characteristic signs of the various complications may appear.

For general, abdominal and cerebral symptoms and complications, see pp. 347, 348.

Course.—This is chronic: the disease often persists for years, without giving rise to any acute disturbance apart from periodic hæmoptysis.

Diagnosis.—Distinction from other forms of hæmoptysis is accomplished by discovering the ova in the sputum. To facilitate the examination a little 0·1 per cent. sulphuric acid should be added to it.

Prognosis.—The immediate prognosis is good, the ultimate unfavourable, as there is considerable difficulty in eliminating the parasites, and permanent damage is wrought in the lungs when they settle there.

Treatment.—Prophylaxis is important where the disease is endemic. No bathing should be allowed in infected rivers, and all water used for drinking or washing should be boiled or filtered. Crabs should not be eaten. When the disease has developed the patient should move from the infected area. Potassium iodide (grs. x-xx, t.d.s.) is recommended, but other treatment is symptomatic.

HYDATID DISEASE OF THE LUNG

Hydatid cysts may develop in the lung in patients infected by the ova of the *Tania echinococcus*.

Ætiology.—Man is the intermediate host of this parasite, and becomes infected directly or indirectly from the dog. The modes of infection and the life-history of the parasite are elsewhere considered. Males are more often affected, and the condition is commoner among the poor than the well-to-do. It is rarely seen in this country except in patients from abroad, especially from Australia.

Pathology.—Hydatid cysts have been described in the lungs in from 5·6 to 16·8 per cent. of cases of hydatid disease in different parts of the world. The right lung is more often the site of the disease than the left, and the cyst is usually basic, though it may occur in the upper parts of the lung. It is generally supposed that infection of the lung is usually secondary to the liver, the ova reaching the lung through the diaphragm; but the occurrence of primary lung hydatid suggests the possibility of the embryo gaining access to the general blood stream, and thus reaching the lung by the pulmonary artery. There is, as a rule, a single cyst in the lung, but multiple or multilocular cysts are occasionally observed. The cyst may become as large as a cricket ball, but usually ruptures before it reaches this size. It has the same structure as hydatid cysts of other organs, with ectocyst and endocyst. It may develop brood capsules and daughter cysts, but is often sterile in this situation.

The reactive changes in the lungs are at first irritative and congestive, but eventually some fibroid changes occur, producing a more or less definite fibroid capsule around the ectocyst. The overlying pleura may become inflamed, thickened and adherent when the cyst grows near the surface. Rupture may occur into a bronchus, into the pleura, pericardium or peri-

toneum, or occasionally into the pulmonary vein. Rarely the contents of a small cyst may become inspissated, thus producing spontaneous cure.

Symptoms.—Until the cyst becomes large enough to cause irritation, there may be no symptoms, but sooner or later cough and expectoration develop. The latter is generally mucoid, and frequently bloodstained. Dyspnoea becomes apparent and pain results if the pleura is involved. The signs may be: diminished vocal fremitus, localised dullness and weak or absent breath-sounds and voice-sounds over a limited area, generally in the lower lobe. A few râles may be audible round the dull area. Occasionally with a large cyst there may be some bulging on the affected side, and “hydatid fremitus” has been described. The heart may be displaced in rare cases. Examination by the X-Rays generally shows a suggestive rounded shadow with very little change in the surrounding lung, except in chronic cases where some fibrosis may be observed.

Some degree of eosinophilia is common but not invariable. When rupture into a bronchus occurs, there is usually sudden copious expectoration of watery fluid containing hooklets. Daughter cysts and parts of the ectocyst may be coughed up and lead to dyspnoea and even suffocation from laryngeal obstruction.

After rupture, spontaneous cure may result if the ectocyst is expectorated. More commonly the cavity becomes infected and the symptoms and signs become those of chronic abscess (see p. 1156). Rupture into the pleural cavity produces great pain, dyspnoea, cyanosis and shock, similar to the condition induced by pneumothorax. Rupture into the pericardium or into a vein is usually quickly fatal. When rupture occurs into a serous cavity, urticaria and severe toxic symptoms sometimes develop.

Course.—This is generally progressive, though occasionally spontaneous cure occurs either before or after rupture. More commonly the cyst causes increasing pressure or irritative symptoms, and eventually rupture or suppuration produces acute manifestations.

Diagnosis.—The clinical features of pulmonary hydatid may be suggestive of pulmonary tuberculosis, pleural effusion or new-growth. Diagnosis may be difficult before rupture occurs; after this the discovery of hydatid hooklets or pieces of cyst-wall may establish the diagnosis. In suspicious cases the X-Ray findings may be of great assistance, and confirmatory evidence may be obtained from cytological and serological examination. The former frequently shows eosinophilia, and the latter gives complement deviation when a suitable antigen such as extract of hydatid cyst-wall, is used. A precipitin reaction may also be obtained with the fluid from another cyst.

Prognosis.—The prognosis is serious owing to the risks of rupture and suppuration. Spontaneous cure is rare, but can occur. After rupture into a bronchus, recovery may ensue, but more commonly abscess formation results. Rupture into a serous cavity is frequently fatal. Early surgical treatment either before or after rupture improves the outlook.

Treatment.—Aspiration of the cyst, either exploratory or therapeutic, is to be avoided. If the cyst can be diagnosed or localised before rupture, the lung should be exposed by thoracotomy, the pleura stitched together and the cyst incised, the endocyst removed, and the cavity drained. Suppuration of a pulmonary hydatid must be treated as a pulmonary abscess.

THE PNEUMONIAS

The term pneumonia has been somewhat loosely applied to any inflammatory condition of the lung producing consolidation. When the consolidation affects large areas of lung uniformly it is described as lobar pneumonia, and when it is patchy or lobular in distribution it is called lobular or broncho-pneumonia.

LOBAR PNEUMONIA

Synonyms.—Croupous or Pleuro-Pneumonia.

Definition.—This is an acute infectious disease characterised by an inflammatory lobar consolidation.

Ætiology.—*Predisposing causes.*—Pneumonia may occur at any age. It is common in children up to the sixth year, the incidence being about equal in the two sexes. It is commonest between the ages of 15 and 40, when there is a preponderance in the male sex of two or three to one. It is also a frequent terminal malady in the aged of both sexes. It may be doubted whether race has much influence, although in America and in the Rand mines the incidence and mortality among the black races are both high. Pneumonia is met with all over the world, but it is more rife in localities with changeable climate and cold winds. Its seasonal incidence is well marked; it is uncommon in the summer and autumn, and is most prevalent from November to March in this country. Although pneumonia is as a rule endemic and sporadic in its incidence, it is generally admitted that localised epidemics occur. Recent studies of its bacteriology lend support to this view. Urban conditions, defective sanitation, overcrowding and insufficient ventilation all conduce to the incidence of pneumonia. A previous attack of pneumonia is an important predisposing condition, since this disease seems to confer an increased susceptibility, although this may be preceded by a brief period of relative immunity. It is not uncommon to obtain a history of several previous attacks. Although the disease often attacks those in normal robust health, there can be no doubt that debilitating conditions and diseases predispose to it, among them being chronic nephritis, diabetes, over-fatigue, exposure and alcoholic excess.

Exciting causes.—The exciting cause in most cases is the presence of the pneumococcus of Fränkel in one of its most virulent forms. It may be the only pathogenic organism found in the lung lesions and in the sputum, but not infrequently others, such as streptococci, staphylococci or Pfeiffer's bacillus are also present. Occasionally these organisms, and others, such as Friedländer's pneumo-bacillus, the *Bacillus typhosus*, the gonococcus and the *B. pertussis*, cause lobar consolidation; but these conditions should be regarded as varieties of secondary pneumonia, and differentiated from the acute primary condition now under consideration.

The pneumococcus.—The pathogenicity of the pneumococcus has been the subject of an interesting study at the Rockefeller Institute, New York, by Cole, Dochez, Avery and Gillespie. By serological reactions they have separated four types. The organisms of types I., II. and III. are clearly

defined and account for about 75 per cent. of the cases of pneumonia investigated. They differ in virulence, type III. producing a more serious form of pneumonia with a high mortality, but fortunately it is the least common form. This organism has a somewhat characteristic morphology and distinctive cultural appearances. It is sometimes described as the *Pneumococcus mucosus*, and is probably identical with the *Streptococcus mucosus* of Schottmüller. Specific agglutinating serums exist for each of these three types. Type IV. is a heterogeneous group of organisms, mostly of low virulence, and no common agglutinating serum exists for them. It is now generally referred to as group IV. They are frequently present in the mouth and saliva of healthy persons, but may cause a mild form of pneumonia with a low mortality, and they are commonly found in pneumococcal lesions in other situations than the lungs. It is probable that other types exist, since F. S. Lister found that among the cases he investigated in South Africa types I. and II. were common, but nearly one third of the cases were associated with one and perhaps two types which were not described in the New York cases.

The American observers have shown that 40 per cent. of contacts with cases of pneumonia due to types I. and II. may harbour the corresponding organism for an average period of 23 days, and that they may develop pneumonia from it. They have further demonstrated that a convalescent patient may carry pathogenic pneumococci in his mouth for as long as 90 days from the onset of the disease. They have also found pathogenic pneumococci in the dust of rooms in which patients suffering from pneumonia have been nursed, whereas in other rooms only the relatively non-virulent type IV. has been found. The significance of this work is obvious. It confirms the view that pneumonia is an infectious disease, capable of being spread by carriers, by the convalescent patient, and by the dust of rooms.

Although the pneumococcus is the specific exciting cause, its activities are often determined by some other factor, such as chill, exposure, over-exertion or injury. The presumption is that these conditions lower the general resistance of the individual, and thus impair the defensive mechanisms. Post-operative pneumonia may be a further instance of this, but doubtless some supposed cases are in reality due to lobar collapse.

Pathology.—The pneumococcus can be found in the blood, in the pulmonary lesions, and elsewhere when complications occur. Recent experimental investigations on animals indicate that the avenue of infection is to the lungs by way of the trachea and bronchi, the blood infection being secondary to the pulmonary lesion. This is in opposition to the view, current till recently, that infection occurred from the mouth or pharynx to the blood and thence to the lungs. Four stages are commonly described in the process by which the lung becomes consolidated and returns to normal, namely, engorgement, red hepatisation, grey hepatisation and resolution.

In the stage of engorgement the affected part of the lung is slightly enlarged, deep red in colour, and heavier than normal, although it still crepitates and floats in water. The pleura over it may be injected and lustreless and may even show early fibrinous exudate. On section, the hyperæmia is obvious and there may be some œdema. On squeezing, frothy, bloodstained fluid exudes. Microscopically, the engorgement of the capillaries, the swelling and partial desquamation of the alveolar epithelium

are the chief changes to be noted. In the stage of red hepatisation the affected area becomes completely consolidated, the general aspect on section being remotely similar to liver, hence the name hepatisation. The pleura is now notably inflamed and may be obscured by yellow fibrinous exudate. The hepatised area of lung is larger and much heavier than normal and bears the impress of the ribs upon it. On section, it is seen to be red in colour, solid and completely airless. It does not crepitate, and it sinks in water. The lung tissue is found to be more friable than normal. On scraping the cut surface, which has a granular appearance, a reddish fluid is collected, containing small fibrinous plugs, which are practically alveolar casts. Microscopically, the alveoli are occupied by a coagulated exudate rich in fibrin and red blood corpuscles, with scanty leucocytes and a few larger cells derived from the alveolar epithelium. In the stage of grey hepatisation the lung tissue, although still solid, airless and non-crepitant, is greyish in colour, softer in consistence and still more friable. The surface of the section is less granular, and on scraping, a pale yellowish, almost puriform fluid is obtained. Microscopically, the blood vessels are found to be relatively empty, the alveoli are now incompletely filled, the fibrin and red corpuscles have largely disappeared, and the alveoli are occupied by leucocytes and desquamated alveolar cells. In the stage of resolution, the exudate becomes more liquid and its cellular constituents undergo fatty degeneration. The liquefied exudate is largely absorbed, although expectoration may possibly assist in its removal. The lung returns to its normal spongy state and the alveolar epithelium is replaced. Some pleural thickening or adhesion may, however, result. In very severe and fatal cases, the stage of resolution may be replaced by one of purulent infiltration, in which the lung becomes paler, softer and in places almost diffuent. The scrapings are practically purulent.

Although these four stages are described, it should be remembered that they are not sharply defined from one another, and that they only represent special appearances in a continuous process. Consequently, although the major part of the affected area of lung may be characteristic of any one of them, all four stages may be recognisable, especially in cases of a spreading type. The base is more often affected than other parts, and the right side more than the left, in the ratio of 3 to 2. The unaffected parts of the lung may show some catarrhal bronchitis, or some degree of collateral hyperæmia or œdema. Pleurisy is an integral part of the affection, but it may proceed to serous or purulent effusion. Pericarditis and less frequently acute endocarditis may be found in fatal cases. Pneumococcal meningitis, arthritis and otitis are very occasionally observed. The liver and kidneys may show cloudy swelling, and the spleen is often slightly enlarged and soft. Jaundice may be observed, especially in right-sided cases. The right side of the heart may be engorged and dilated.

Symptoms.—The exact incubation period is not yet established, but it is short, being probably from 1 or 2 days up to a week. The onset is sudden and acute, with chill, shivering or rigor in the majority of cases. In children convulsions take the place of rigors. Vomiting at the onset is not infrequent, occurring in about one-third of the cases. Less commonly the onset is insidious, or is preceded by malaise and catarrhal symptoms. The temperature rises with the rigor, and as a rule a short, dry, irritating cough develops quickly, accompanied by a severe cutting pain on the affected side. The

pain often becomes intense, and coughing may cause the patient great distress. The cough is frequently restrained as much as possible, and the breathing is rapid and shallow. By the second or third day the pain becomes less and the cough easier and more effective. Sputum, which at first is scanty, extremely viscid, tenacious and difficult to expectorate, now becomes more abundant, although remaining viscid. In typical cases it is characteristically rusty at this stage, containing mucus, altered red blood corpuscles, alveolar epithelium and large numbers of pneumococci. In a few instances a small but definite hæmoptysis occurs. Occasionally the sputum is thinner and of "prune juice" type.

Sleeplessness is often a distressing symptom, especially in the early and late stages. In some cases there are marked cerebral symptoms. Headache at the onset is common. Delirium is frequent, particularly in the asthenic type, in apical cases, and in alcoholics. In the latter it may be violent and is often like delirium tremens. The temperature is usually of high continuous type throughout, reaching 103°, 104° and even 105° F. or more on occasions, especially in the sthenic type. In the asthenic it is often of lower range. Defervescence is by crisis in about 60 per cent. of the cases. Crisis is commoner in the sthenic type, and occurs more often on the odd than on the even-numbered days of the disease. The most common day for the crisis is the seventh. It is rare before the third or after the ninth day. At the crisis the temperature falls to normal or subnormal in about 12 hours. The patient often sleeps soundly at this time and may sweat profusely; respiration is slower and easier and the pulse-rate falls. On waking, a dramatic change in the condition is usually noticeable. Pain and distress are ameliorated, cough is loose and easy, and the patient feels better, although weak. Looseness of the bowels and free diuresis are not infrequent, constituting the "critical evacuations." The crisis is sometimes preceded by a pseudocrisis, in which a considerable fall of temperature occurs, with little or no improvement in the general condition. A slight post-critical rise of temperature of 1° or 2° F. is sometimes seen, but as a rule the temperature remains subnormal for a few days and slowly returns to normal. The pulse-rate may be slow for a time. Convalescence is generally rapid, although in cases which have had marked delirium, some mental confusion may be present for a day or two. Defervescence by lysis is more common in the asthenic type. The temperature remits and may take from 2 to 4 days to reach normal or subnormal levels.

The physical signs vary with the stage of the disease. At first there is some restlessness, but soon the patient assumes a dorsal decubitus, or lies more on the affected side. The cheeks are flushed, often markedly so on the side of the lesion. The eyes are bright, but the expression is one of pain or anxiety. A crop of herpes on the lips is very common. The tongue is thickly coated and white, becoming dry and cracked in bad cases at a later stage. The skin feels dry and pungently hot. The *alæ nasi* are in action, and in children a puff or grunt accompanies each expiration, while the pause follows inspiration, instead of expiration. The respiration and pulse-rate are increased, the former disproportionately, so that the pulse respiration ratio becomes 3 or even 2 to 1, instead of the normal 4 or 5 to 1.

In the early stage the pulmonary signs are slight. At the most there is lessened movement and diminished vocal fremitus over the affected area,

1202 DISEASES OF THE RESPIRATORY SYSTEM

with dubious impairment of note, weak air entry and possibly a few crepitations (indux), or pleural friction sounds, vocal resonance being unaltered. Of these, lessened air entry is probably the most common. Slight hyperresonance of the opposite lung, with harsh breathing, may lead to error in diagnosis as to the side affected.

The signs of consolidation (hepatisation) are generally apparent on the second or third day, except in cases where the disease starts deeply (central pneumonia). There is definite limitation of movement on the affected side, which is, however, slightly increased in size, as can be demonstrated by mensuration. Vocal fremitus is markedly accentuated over the affected area except in massive pneumonia, and friction fremitus may be palpable. The note on percussion is dull, but has not the resistant stony character of that over an effusion. The note above or below the consolidated area is sometimes skodaic. The breath-sounds are tubular, and a few crepitations may be heard, but frequently adventitious sounds are absent. In some cases a friction rub is audible. Bronchophony and pectoriloquy are usually very marked over the consolidated area. The breath-sounds in other parts may be vesicular or harsh, and a few rhonchi may be present. The heart is usually in its normal situation, but is sometimes slightly displaced away from the affected side. In later stages the signs of dilatation of the right heart may become apparent.

During resolution, which begins after the crisis or during lysis, the tubular character of the breath-sounds disappears, and they become at first bronchial and later harsh or vesicular. Coarse moist sounds, known as *redux* crepitations, are heard both with inspiration and with expiration. The dullness gradually diminishes, and the voice-sounds return to normal. In basal cases, in which the diaphragmatic pleura is involved early, there may be pain, tenderness and abdominal rigidity simulating peritonitis, perforation or appendicitis. X-Ray examination is usually not practicable, and in any case should only be employed where diagnosis is in doubt. It is rare for the spleen to be sufficiently enlarged to be palpable. The blood shows a leucocytosis up to 40,000 or 50,000 per c.mm. in sthenic infections. Blood culture may yield pneumococci, although this was successful in only 30 per cent. of cases at the Rockefeller Institute. The urine is diminished in quantity, and there is a great reduction in the sodium chloride excretion until the crisis. Albumin and albumose are frequently found in small quantities in the urine during the febrile stage, and a few granular casts may be present. The uric acid excretion is increased to two or three times the normal, commencing the day before the crisis and generally falling to normal during the ensuing week. This is probably due to disintegration of the exudate in the alveoli, and so forms a measure of resolution, although some authorities maintain that it runs parallel with leucocytosis and not with cell destruction. Palmer has recently shown that an organic acid of unknown nature is excreted in the urine in considerable quantities in many cases of pneumonia with severe intoxication, but estimation of the CO_2 in the plasma shows that the degree of acidosis produced is not great. Pneumococci can sometimes be obtained from the urine at the height of the disease. The blood-pressure usually falls during the course of pneumonia, and according to G. A. Gibson a sudden rise indicates the imminence of some complication, such as delirium, whereas a sudden fall suggests the onset of cardio-vascular paralysis.

The disease does not always follow the typical clinical*course, and certain varieties are described :

Apical pneumonia.—The consolidation may be limited to the apex or upper lobe of one lung. This is more common in children, the aged and alcoholics, and is often associated with marked cerebral symptoms.

Creeping pneumonia (Migratory or wandering pneumonia).—The consolidation spreads irregularly in one or both lungs. Partial resolution occurs, but there is no true crisis, and as successive portions of the lungs become involved the temperature exacerbates, eventually falling by lysis in cases that recover.

Central pneumonia.—The symptoms and appearance of the patient may suggest lobar pneumonia, and yet no abnormal signs can be detected in the lungs. In some of these cases there may be a deep-seated consolidation, whose presence can be revealed by X-Rays. A typical crisis may occur.

Massive pneumonia.—The bronchi, as well as the alveoli, may be filled with a fibrinous exudate. It is a rare condition and leads to difficulty in diagnosis, as the physical signs resemble those of pleurisy with effusion, vocal fremitus being diminished and breath-sounds weak or absent. The heart, however, is not displaced, or only slightly so.

Post-operative pneumonia.—It is probable that a large proportion of cases that were formerly described as post-operative pneumonia were in reality instances of massive lobar collapse (see p. 1143). At times a pneumococcal pneumonia follows the administration of a general anæsthetic, but it does not present any peculiar features.

Traumatic pneumonia.—The fact that an injury to the chest may be followed after a short interval by a pneumonic process in the lungs has long been recognised. The condition was called "contusional pneumonia" by Litten in 1881. Külbs showed later that the changes in the lungs in dogs following local trauma were mainly hæmorrhagic, and that the lung opposite to the side injured may be affected by "contre-coup." In the recorded cases of traumatic pneumonia two types can be differentiated—(1) those with hæmorrhagic lesions only, and (2) those showing hæmorrhagic foci with a superimposed bacterial infection. The former recover rapidly, the latter often lead to a fatal issue.

Pneumonia in children.—This often presents certain characteristic features. There is rarely any sputum, the expectoration being swallowed. Convulsions at the onset are common. The lesion is often at the apex of the lung. Cerebral symptoms are frequent, and empyema or otitis media often occurs as a complication.

Pneumonia in the aged.—This occurs frequently as a terminal infection, often leading to a rapid and comparatively painless death. The onset may be insidious and the physical signs slight.

In *pneumonia in the insane*, lobar consolidation is often observed, without marked constitutional disturbance other than fever.

Secondary pneumonia.—Lobar pneumonia may develop during the course of certain acute specific fevers, notably enteric, typhus and plague. It is doubtful whether a true lobar pneumonia occurs in influenza, the condition to which the name influenzal pneumonia is applied being due to coalescing lobular pneumonia with hæmorrhagic extravasations.

Complications.—Delayed resolution not infrequently occurs, the signs

of consolidation persisting for weeks instead of days. Frequent careful examinations should be made and possible errors in diagnosis considered, such as the presence of tuberculosis or empyema. Gangrene and abscess are rare but recognised complications.

Dry pleurisy is an invariable accompaniment when the consolidation reaches the surface, and in a considerable proportion of cases slight serous effusion occurs. This occasionally becomes frankly purulent and an empyema results. Bronchitis is common and may be due to a complicating secondary infection. Cardiac failure is a grave occurrence and can be recognised by increasing cyanosis, lividity and dyspnoea, with signs of enlargement of the right heart and with enfeeblement of the heart-sounds. Pericarditis is not very uncommon and is a serious complication. It may be dry or proceed to serous or purulent effusion. Acute endocarditis, sometimes of infective type, occurs. Abdominal complications are comparatively rare. They include pneumococcal peritonitis, colitis and nephritis. Acute dilatation of the stomach occurs in rare cases, and is usually rapidly fatal. Meteorism is more common and, although serious, is more amenable to treatment. Jaundice, due to catarrh of the bile-ducts, or to hæmolysis, is sometimes present.

Pneumococcal meningitis supervenes in rare cases, and is invariably fatal. Delirium has already been referred to, and is especially serious when occurring in alcoholics. Peripheral neuritis has been described, but is very uncommon. Otitis media and arthritis, proceeding sometimes to suppuration, occur as complications, both being commoner in children. A parotitis, sometimes going on to suppuration, is an occasional and serious complication, especially in old people. During convalescence, thrombosis of the veins of the legs may occur in rare instances.

Sequelæ of lobar pneumonia are uncommon. Perhaps the most remarkable is the liability to subsequent attacks. Some permanent pleural thickening or adhesion may occur, and after an empyema the usual sequelæ may result. Pulmonary fibrosis (chronic interstitial pneumonia) is rare, especially in comparison with its frequency after broncho-pneumonia; this may lead to bronchiectasis.

Course.—The course depends on the type and virulence of the infection and on the resistance of the patient. In a typical sthenic case, consolidation is well established by the second or third day, defervescence by crisis occurs usually on the seventh day, signs of resolution become apparent a day later, and all signs clear up within 14 days of the onset. In asthenic cases the course is less typical and often prolonged to 9 or 10 days, defervescence occurring by lysis. In fatal cases, death commonly occurs between the fourth and tenth days, although severe cases may prove fatal as early as the first or second day. After the tenth day a fatal result is generally due to complications. An abortive course is described, in which typical symptoms occur with slight or indefinite signs, the temperature falling by crisis within 36 hours, followed by rapid recovery. This group includes the "*maladie de Woillez*." It is difficult in many instances to establish the true causation of such cases.

Diagnosis.—When the disease is well established and the history is available, diagnosis is as a rule easy. To prove the pneumococcal origin, sputum examination, lung puncture, or blood or urine culture is necessary. It would seem probable that in the future the investigation of serum reactions will

be necessary to establish the type of pneumococcus concerned as an essential to specific treatment.

At the onset, especially before the signs of consolidation develop, difficulties in diagnosis often occur. The initial rigor or convulsion with vomiting may suggest scarlet fever. In children, especially those with early apical pneumonia, headache, vomiting, convulsions, head retraction, squint and even slight Kernig's sign may lead to an erroneous diagnosis of meningitis. Pain in the side and cough, the altered pulse respiration ratio, and the presence even of slight abnormal physical signs in the chest, usually suffice in both instances to suggest the correct explanation.

Occasionally the onset of pneumonia may simulate an acute abdominal condition, such as appendicitis or perforation of a gastric ulcer, owing to referred abdominal pain, sometimes with rigidity. The diagnosis may be very difficult, and laparotomy has not infrequently been carried out in error. The history, the pulse respiration ratio, the absence of tenderness on rectal examination, and the presence of pulmonary signs usually enable a correct decision to be made.

Influenza may start acutely and simulate pneumonia, but the distribution of the signs and the examination of the sputum generally serve to distinguish between them. Typhoid fever less often gives rise to difficulty, but some cases of pneumonia pass quickly into a typhoid state, while some cases of typhoid fever develop consolidation in the first week.

When consolidation is well established, the chief conditions to be differentiated are—(1) Broncho-pneumonia. The slower onset, the more prolonged course, the bilateral patchy physical signs, and the marked predominance of the bronchitic manifestations usually suffice to differentiate this group of conditions. (2) Secondary pneumonias, such as those in plague, typhoid fever, and influenza, can be diagnosed only from the history, the associated symptoms and signs, and from the bacteriological examinations. (3) Friedländer's pneumonia is rare. Its course is short, its prognosis grave, and it can only be recognised by bacteriological investigation. (4) Massive collapse. The diagnosis of this condition and its differentiation from pneumonia are discussed on p. 1144. (5) Acute pneumonic tuberculosis. The onset and early signs may be identical with those of pneumonia. The persistence of the fever, its tendency to become remittent or intermittent, and the occurrence of night sweats should suggest looking for tubercle bacilli in the sputum. (6) Pleural effusion and empyema. Differentiation is generally easy, except in cases of massive pneumonia. Investigation of the position of the cardiac impulse, and of vocal fremitus and resonance, affords the most valuable aid. Grocco's triangle may also assist. In some cases the diagnosis can only be established by the exploring needle. (7) Infarction of the lung in cardiac disease, causing pain, cough, blood-stained expectoration, and dyspnoea, may simulate pneumonia. The absence of fever, the presence of the cardiac condition and the localised physical signs are generally characteristic. (8) Acute oedema of the lung, especially in mitral stenosis, may suggest pneumonia. Fever is generally absent, the sputum is typical, and the primary cause may be apparent. An attack of paroxysmal tachycardia may give rise to difficulty, when it leads to dullness and crepitations at the bases, but careful examination should establish the very rapid action of the heart and the evidence of venous engorgement in other parts.

Prognosis.—Löbar pneumonia is a serious disease, with a high mortality rate. This is profoundly influenced by age. It is but little fatal in childhood, except in the first years of life. After the age of 60, it may show a mortality of 60 to 80 per cent. The New York investigations at the Rockefeller Institute have demonstrated the importance of the type of pneumococcus in prognosis; thus, it was found that the mortality of cases with types I. and II. was about 25 to 30 per cent., of those with type III. 50 per cent., and of those with type IV. only 12 per cent.

The previous habits and history of the patient influence prognosis considerably; chronic alcoholism doubles the risk of a fatal issue, and the outlook is grave in patients who are the subjects of diabetes, chronic cardio-vascular disease, nephritis, marked debility or obesity. Unfavourable indications during the course of the disease are profound toxæmia, a pulse-rate persistently 130 or more, a blood-pressure in millimetres of mercury lower than the pulse-rate, and a temperature remaining at 105° F. or over for several days. Absence of the usual leucocytosis is generally of sinister import. Dilatation of the right heart, with cyanosis progressing to lividity, is most grave. Modern statistics confirm the traditional view that labial herpes is a favourable prognostic sign.

Of complications, meningitis is invariably fatal, while septic endocarditis is extremely grave. Cases with abscess or gangrene, although serious, sometimes recover, especially if operative treatment is practicable. The prognosis of those with pericarditis is serious, but not uniformly unfavourable. Cases with bilateral empyemata show a high mortality. Late delirium is a very serious indication.

Treatment.—*Prophylactic.*—Prophylactic vaccination has been used with success by Lister in South Africa. He employed a triple vaccine, made from three types, and gave 6000 millions of each. Three injections were made at weekly intervals.

When a case has occurred, all contacts should have a throat examination, and if virulent pneumococci are found a suitable antiseptic mouth wash should be used. Quinine preparations have a high pneumococcicidal action. The best is optochin or ethyl-hydrocupreine hydrochloride, or else quinine bisulphate in a dilution of 1 in 10,000 with liquor thymolis diluted 1 in 10. The room in which the patient has developed the disease should be disinfected afterwards. If possible, no case of pneumonia should be nursed in a general ward of a hospital, and the doctor and nurse in attendance should wear gauze masks. All sputum should be disinfected. The patient should lie in a narrow bed away from a wall to facilitate nursing. The room should be well ventilated, and the temperature maintained at 60° to 65° F. Treatment in the open air is not advisable except in very mild weather. Two important factors are rest and sleep. The patient should, therefore, be disturbed as little as possible by the examination of the physician and by the attentions of the nurse. He should not, however, be allowed to lie flat all the time, to avoid basal congestion. The diet should be restricted to fluids and semi-solids, eggs, milk, meat extracts and the various invalid foods being given up to 2 or 3 pints in the 24 hours. Glucose, in the proportion of 2 to 4 ounces to the pint of lemonade or orangeade, is useful. Too much milk should be avoided, as it is liable to cause indigestion and flatulence. The irritating cough, which induces such intense pain, should be checked

by a sedative linctus, or by lozenges, but it may be necessary to inject $\frac{1}{2}$ th grain heroin, or even $\frac{1}{4}$ th grain morphine to relieve pain and to induce sleep in the early stage. Local applications to the chest help to relieve pain. Usually hot linseed poultices to the back and side are employed, but anti-phlogistine applied on lint does not require such frequent changing and disturbs the patient less. A pneumonia jacket is preferred by some, by others the ice poultice or ice-bag is found very soothing.* A dose of calomel should be given at the onset, and the bowels should be opened daily, either by a laxative or by a small soap enema.

Medicinal treatment has probably but little influence on the course of the disease, and should be in the main symptomatic. In the early stage, a simple saline diaphoretic mixture may give comfort by promoting the action of the skin and by rendering the sputum less viscid. For this purpose liq. ammon. acetat. $\mathfrak{z}\mathfrak{i}$, potass. citrat. grs. xx, syrup. aurantii $\mathfrak{z}\mathfrak{i}$ and water to the ounce, may be given every 4 to 6 hours. The use of depressant drugs, such as tartar emetic, aconite, or pilocarpine, although formerly recommended, is now generally discarded. Expectorants such as ammonium carbonate or iodide of potassium in doses of 3 to 5 grains are often recommended after the second day, but are of doubtful utility. Potassium iodide in doses of 5 to 10 grains, with creosote 5 minims, in a mixture, had a recent vogue, but it may be doubted whether its beneficial effects are commensurate with its unpleasantness and its bad influence on appetite and digestion.

Cardiac embarrassment and failure are the conditions requiring the most active treatment in this disease. A careful watch should be kept upon the colour of the patient, the condition of the pulse and the size of the heart. Digitalis, in doses of 5 to 15 minims of the tincture, may be added to the mixture, or given with brandy. Camphor grs. xx, in sterile olive oil $\mathfrak{z}\mathfrak{i}$, may be given hypodermically every other day, or smaller doses may be given once or twice daily. If signs of acute heart failure occur, strophanthin gr. $\frac{1}{100}$ may be given intravenously, or digitalin gr. $\frac{1}{100}$ with strychnine sulphate or hydrochloride gr. $\frac{1}{80}$ to $\frac{1}{30}$ hypodermically. The latter may be repeated in from 4 to 6 hours if necessary. Strychnine may be given in doses of gr. $\frac{1}{80}$ every 4 hours, and is often very useful. Other cardiac tonics which may be employed hypodermically are pituitrin $\frac{1}{2}$ to 1 c.c., or adrenaline 5 to 10 minims of 1 in 1000 solution. Alcohol is often useful; it should not be given too early in the attack, but where there are indications of incipient cardiac weakness 4 to 6 ounces daily may be given, and this even to alcoholics.

Oxygen inhalations may be helpful in any case where there is distress or cyanosis. It should be warmed, and may be bubbled through alcohol or administered more economically through a nasal tube. Venesection to the extent of 10 or 12 ounces is of some value if there is lividity from right-sided engorgement, especially in sthenic cases. As a rule it is best not to interfere with the temperature by antipyretic drugs and measures unless it remains over 104° F., when sponging, either tepid or cold, should be tried.

Sleeplessness is a frequent and distressing symptom and requires treatment. In the early stages 10 grs. of Dover's powder or an injection of morphine or heroin are usually effective. In the later stages, morphine should only be given with care, and then in association with atropine gr. $\frac{1}{80}$ to $\frac{1}{100}$ and strychnine gr. $\frac{1}{80}$ to $\frac{1}{30}$. Paraldehyde $\mathfrak{z}\mathfrak{i}$ with syrup of orange in 2 ounces of water, is safe and often effective. Chloralamide grs. xx to xxx, with

1208 DISEASES OF THE RESPIRATORY SYSTEM

bromides may be tried. In cases with delirium an ice-cap should be applied to the head, and the patient sponged with tepid water. Morphine may be necessary, and in severe cases hyoscine, gr. $\frac{1}{100}$, may be injected; but the latter is a dangerous drug and the patient's condition should be watched, and strychnine administered if necessary. Tympanites, when present, is distressing and exhausting, and should be treated by passing a rectal tube or by the administration of an emema of asafoetida or a turpentine wash-out.

Specific.—Various serums have been introduced and employed with varying success. The researches at the Rockefeller Institute afford the explanation of the discordant results, and promise to put this matter on a scientific and practical basis. So far an effective serum seems to have been obtained only for type I., although serum has been prepared for type II. but is less effective. At present antisera have not been obtained for type III. and group IV. A new specific serum, highly concentrated, has been introduced by Felton. It is said to be of great value in type I. cases and to be helpful in type II. cases. Consequently, if it is proposed to employ serum treatment it is necessary first to determine the type of pneumococcus concerned by serological tests. A rapid method involving the testing of the organisms in the fresh sputum against a test serum has been introduced by Armstrong. The patient's sensitiveness to the serum must then be determined by an intradermic injection of 0.02 c.c. of diluted serum (diluted $\frac{1}{10}$ with saline), and if he shows a reaction he must be desensitised by small injections to prevent anaphylaxis. The serum is then diluted with an equal volume of warm sterile saline and 10 to 15 c.c. injected intravenously at the rate of 1 c.c. a minute, followed by 90 c.c. more during the next quarter of an hour. This dose is repeated every 8 hours until improvement occurs. Felton's serum (2000 units in 1 c.c.) is administered intravenously undiluted, after being warmed to body temperature and after careful preliminary tests as to sensitiveness. The initial dose is 10,000 units, slowly injected intravenously. Amounts up to 40,000 or 50,000 units are given in the first 24 hours, though as much as 100,000 units may be necessary in severe cases. The earlier it is given, the greater is the likelihood of success.

Vaccine treatment is recommended by some, but the results are generally disappointing during the acute stage. A common method is to give 20 millions of a stock pneumococcus vaccine, and then to use an autogenous one as soon as it can be made. Sensitised and detoxicated vaccines have also been prepared. Vaccines seem to be more valuable in cases of delayed resolution.

Artificial pneumothorax has been suggested as a primary method of treatment. There is as yet no convincing evidence of its value, but in cases with severe pain, the introduction of sufficient air to separate the inflamed surfaces of the parietal and visceral pleura is worth considering.

BRONCHO-PNEUMONIA

Synonyms.—Lobular Pneumonia; Catarrhal Pneumonia; Capillary Bronchitis.

Pulmonary consolidation of lobular distribution occurs in a variety of conditions which have little else in common. A satisfactory classification is at present difficult. The term capillary bronchitis is misleading and should

be regarded as obsolete, since any inflammatory condition affecting the finer bronchi is invariably associated with alveolar changes. For convenience the following varieties of broncho-pneumonia may be described: (1) Primary. (2) Secondary. (3) Aspiration or deglutition. (4) Tuberculous.

1. PRIMARY BRONCHO-PNEUMONIA

Ætiology.—This form almost invariably affects infants under 2 years of age, in whom a lobular pneumonia seems sometimes to occur under conditions which would induce lobar pneumonia in older children or adults. It occurs equally in the two sexes, and is commoner in the winter and the spring. Rickets, malnutrition and debility are predisposing conditions, but it sometimes develops in healthy robust infants after exposure or chill. The pneumococcus is the organism usually found, either alone or in association with others, such as streptococci, staphylococci, the *Micrococcus catarrhalis* or Friedländer's pneumo-bacillus.

Pathology.—Widely scattered patches of consolidation are found in one or both lungs. These may be small and separated by areas of collapse or emphysema. Occasionally they are almost confluent, and at first sight appear like lobar pneumonia, constituting the pseudo-lobar form; but careful observation shows that the distribution is lobular and that zones of incomplete consolidation or of normal lung tissue separate the solid areas. If the process reaches the surface some degree of pleurisy is present, although this is less than in lobar pneumonia.

Microscopically, the appearances approximate to those of the lobar form; the alveoli are found to be filled with exudate, in which leucocytes and desquamated epithelial cells are present, together with some fibrin and red blood corpuscles. Catarrhal changes are also present in the bronchi.

Symptoms.—The onset is acute, with vomiting and chill, or convulsion, as in lobar pneumonia. Cough, cyanosis and dyspnoea develop rapidly. There is no expectoration, since infants and young children swallow the sputum. Cerebral symptoms simulating meningitis are common. The temperature rises quickly to 103°, 104° F., or higher, and the range is of the same character as in lobar pneumonia. Defervescence by crisis is the rule.

The physical signs are variable. In cases with widespread consolidation they are very similar to those of lobar pneumonia, with dullness, tubular breathing, increased voice-sounds and crepitations. In other cases, although the aspect of the infant appears characteristic of pneumonia, with rapid breathing, cyanosis, reversed rhythm of inspiration and expiration, sucking in of the lower ribs and dilatation of the *alæ nasi*, the signs are more scattered. Tubular breathing and increased voice-sounds may only be heard in localised patches, especially in the lower lobes. Crepitations are commonly present, and rhonchi may be audible over both lungs.

Complications and Sequelæ.—These are similar to those of lobar pneumonia.

Course.—This is usually short, the temperature falling by crisis in from 3 to 7 days, but it may be more prolonged and be suggestive of tuberculosis, or some other form of secondary bronchitis.

Diagnosis.—Primary broncho-pneumonia has to be distinguished from
